On August 14th, 1922, a girl, aged 12 years, fell off a pony. The right upper extremity was pinned between her back and the ground. When seen on August 16th there was much pain and swelling. The elbow had been vigorously rubbed with some liniment. Crepitus was felt, but the site of fracture was uncertain. A skiagram showed a fracture of the neck of the radius, with slight ulnar displacement of the lower end of the upper fragment.

The limb was put on an internal angular splint in semi-pronation. On August 23rd passive movements of flexion and extension were commenced. On September 7th general passive movements and massage were instituted. On September 18th the patient was allowed to ride. Examination on September 29th revealed complete and perfect recovery.

Burton-on-Trent.

## Reports of Societies.

## BONE-GRAFT SURGERY.

At a meeting of the Edinburgh Medico-Chirurgical Society on January 17th, with the Vice-President, Sir DAVID WALLACE, in the chair, Mr. A. E. MORISON read a communication on the principles of bone-graft surgery. In a large proportion of cases, he said, the two points requiring special consideration were the presence of latent sepsis and of scar tissue. He emphasized the importance of elimination of latent sepsis. As regards the detection of this, his experience was that the employment of radiant heat was the most reliable and constant guide; he used a 2,000-candle power lamp applied to the seat of injury for increasing periods of five to fifteen minutes each day, the course of exposure lasting ten days. His custom was to carry out the operation in two stages. At the first the scar tissue was widely excised, the ends of the bone examined, the wound treated with alcohol, bipped, and then closed with silkworm sutures; when the radiant heat test was negative the second part of the operation was performed. While the test was still positive autogenous vaccines were employed. Further, before operation was undertaken free movement in the joints and tendons of the affected limb must be secured and the patient accustomed to the retentive apparatus and the attitude of the limb to be adopted later. The fibula, the antero-internal surface of the tibia, and the crest of the ilium were useful sites from which to transplant bone. Where a bridging graft was employed the length of the graft should be three times that of the gap. In removing the graft the periosteum was cut with a knife and the bone with an Albee saw kept cool with saline; the periosteum was retained in all but intramedullary grafts. Mr. Morison then proceeded to describe the various types of graft suitable for different cases. The indications of the inlay—intramedullary "cricket-bat," "cricket-bail" and "wedge-shaped" varieties—were fully discussed. Methods were described of fixing the graft by absorbable sutures, such as catgut and kangaroo tendon, and by non-absorbable sutures, such as wire. The use of split pins, bolts, and metal bone plates was fully dealt with, and other details of technique were given.

The paper was discussed by Professor CAIRD, Mr. MILES, Mr. SCOT SKIRVING, Mr. MERCER, and Mr. SHAW.

## "Occupation Cure" in Neurasthenia.

Dr. A. J. BROCK then read a communication on the "occupation cure" in neurasthenia. Experience proved that in most of the psychoneuroses the mental factor should be considered first, although all psychological phenomena were doubtless accompanied by physical and chemical changes in the nervous tissue. The mind foolishnesses of everyday life were dealt with by moral means; why not then also severer phenomena of the same kind? The renewed interest in psychology which centred round Freud might be compared with that which a century ago found its chief spokesman in Gall, at a time of social and mental stress resembling the present. Gall, like Freud, emphasized subconscious trends, but through undue importance being attached to cerebral localization of the "propensities" and through general oversystematization at the hands of Gall's followers his teaching lost repute and degenerated into phrenology. In Edinburgh George Combe, in particular, developed the educational side of Gall's psychology. Freud had recently re-emphasized the subconscious; his stressing of sexuality and psychological determinism applied mainly to pathological cases. For a complete hygiene of mind the psychology of Freud must be supplemented by that of a vitalist such as Bergson. Coué had lately demonstrated another prevalent pathological condition—the extreme suggestibility, hypnotizability, even gullibility, of the popular mind. As regards treatment, apart from cases with definite complexes, needing psycho-analysis, there were many patients with merely a diffused fearfulness or tendency to worry; these dreaded exerting themselves (ergophobia) and should by ergotherapy be stimulated to strengthen their wills. Their work should be congenial, and, man being a sociable animal, their work must be related to that of their social milieu. Education, by divorcing the child from its environment and presenting knowledge as unconnected school "subjects," predisposed to mental dissociation. The programme of the Regional Survey Association found a basis for correlation of all subjects of study in the individual's immediate environment, and hence should appeal to the medical

re-educator no less than to the teacher. Education being preventive mental medicine, co-operation between doctors and educationists was urgently needed.

The paper was discussed by Drs. BLAIKIE, GARDINER, RITCHIE, STEVENS, and WALKER.

#### Clinical Cases.

The following clinical cases were exhibited: by Mr. D. P. D. WILKIE, a case of pseudo-coxalgia or osteo-chondritis deformans juvenilis; by Dr. FERGUS HEWAT, a case of mediastinal tumour; by Dr. ALEX. GOODALL, a case of progressive muscular atrophy in a boy; by Dr. W. T. RITCHIE, a case of muscular dystrophy.

### THE FRACTIONAL TEST MEAL IN GASTRIC AND DUODENAL ULCER.

A MEETING of the Manchester Pathological Society was held on January 17th, with the President, Professor SHAW DUNN, in the chair, when Mr. E. F. GUY read a paper entitled "The fractional test meal and the information obtained from it in ulceration of the stomach and duodenum." His paper was based on an analysis of 60 cases from a surgical clinic, in 36 of which the presence of an ulcer had been confirmed at operation. He had found a hyperacid resting juice in duodenal ulcer, with a continued high acidity persisting after emptying of the stomach. On the motor side there was "hurry," emptying taking place in less than the normal two and a quarter hours. In gastric ulcer, particularly in ulcer of the body of the stomach, the acidity was generally low and emptying was delayed. Blood might be present in both duodenal and gastric ulcer. With pyloric ulceration stasis was a prominent feature even when the pyloric ring was free, with an acidity which rose to a high level during the digestion of the meal. The resting juice in this category was low and the after-secretion not commonly very acid. Mr. Guy showed charts of cases before and after operation, demonstrating that the amount of reduction of acidity was not constant, but depended on the character of the gastric secretion before operation. Even after pylorotomy the acidity might remain high, and after this operation emptying was often very hurried.

Mr. GEOFFREY JEFFERSON, on whose cases these tests had been carried out, said that he thought the charts showed in concrete form facts of which they had before been clinically aware. For instance, the commonly excellent results following gastro-enterostomy were explained by the improvement in the rate of emptying of the stomach, and the acid secretion accompanying ulcer in this situation was not of a character likely to lead frequently to after trouble. In duodenal ulcer the relatively high acidity which remained after gastro-enterostomy no doubt accounted for the troubles (including secondary ulceration) which sometimes followed. The method yielded valuable information in cases where operation had not given a perfect result.

#### Specimens and Cases.

Dr. T. M. BRIDE showed four specimens of sarcoma of the choroid, two pigmented and two non-pigmented. He estimated the frequency of the condition as 1 in 3,000 cases examined, and asked for information from the members on the late results of those cases. Dr. CORSAE STURROCK mentioned two cases that he had seen where death occurred from secondary deposits in the liver within two years after enucleation of the eyeball.

The President and Dr. BOSDIN LEECH described an unusual case with post-mortem findings clearing up the diagnosis. It concerned a boy, 3 years of age, who had dullness of the left chest and dyspnoea of a stridulous kind. This continued for two and a half months, the temperature remaining normal, until the child died rather suddenly. Examination by Professor Shaw Dunn revealed a minute piece of fish bone embedded in the right side of the larynx. There was perichondritis and absorption of cartilage cells. The afebrile course of the consequent bronchopneumonia was remarkable.

Dr. ARNOLD JONES showed a case of cavernous haemangioma of the vocal cord in a man 45 years of age. This he removed successfully by the indirect method. He remarked on the rarity of the condition, there being apparently only 73 cases in the literature.

Dr. HILLYARD HOLMES showed the kidneys from a case presenting signs which led to the diagnosis of "essential haematuria." Urinary bleeding was severe and the patient died in a uraemic state. At autopsy small granular kidneys

were found, and Dr. Holmes remarked on this fact as being a likely explanation for many cases of so-called "essential haematuria." Dr. Holmes showed also a ruptured aneurysm of the middle cerebral artery in a non-syphilitic man of 38. Professor SHAW DUNN said that aneurysms were a commoner cause of cerebral haemorrhage in young people than was generally recognized; they might occur in childhood, and he commented on the peculiar fragility of the cerebral vessels as a class.

Mr. E. E. HUGHES showed some curiously shaped calculi found by chance in the bladder of a man of 65 at necropsy.

### INFLUENCE OF INTESTINAL BACTERIA UPON THE THYROID GLAND.

At a meeting of the Cardiff Medical Society on January 16th, with the President, Professor EWEN J. MACLEAN, in the chair, Mr. D. J. HARRIES read a paper entitled "The influence of intestinal bacteria upon the thyroid gland." He first drew attention to Professor Kendall's discovery that thyroxin was a tri-iodo-tri-hydro derivative of tryptophane, an amino-acid normally produced in the intestine during digestion of proteins, and then gave a short account of the normal flora of the intestine, dividing it into two main groups—(1) fermentative and (2) putrefactive. Both groups were normally present in the human intestine; in lower animals it was possible to destroy the putrefactive group by administering carbohydrates, especially lactose and dextrine; but unfortunately this was not possible in a healthy human being.

In a series of experiments on guinea-pigs Distaso and Harries had shown that the presence of indican in the urine depended on the presence of putrefactive organisms in the intestine, and that the disappearance of the latter coincided with the disappearance not only of the indican, but of all the organic sulphates, from the urine. This was important, as it explained the sympathetic symptoms in exophthalmic goitre. In another series of experiments the speaker had shown that in exophthalmic goitre the indican and other organic sulphates in the urine diminished as the symptoms increased, and they ultimately disappeared in serious cases, and only reappeared during recovery from the disease. In ordinary parenchymatous goitre there was no diminution, but often an excess, of indican and all organic sulphates. In those cases any diminution in the indican suggested the onset of exophthalmic symptoms. Parry Morgan's recent work on some of the speaker's cases agreed with the results obtained by Distaso in lower animals. He found very few colonies of putrefactive organisms on media inoculated with faeces from exophthalmic goitre cases.

The treatment of goitre cases was next considered in detail, and the choice of diet in particular cases was gone into. It was pointed out that partial thyroidectomy in exophthalmic goitre reduced the symptoms by diminishing the size of the gland and therefore its capacity for manufacturing thyroxin from the tryptophane absorbed; the amount of tryptophane absorbed depended, naturally, on the food taken and on the amount converted into indole and skatole by the putrefactive organisms in the intestine. The prognostic value of the urine examination for indican was also emphasized, as its absence in early cases of exophthalmic goitre was of grave significance. The methods for re-establishing a putrefactive flora in exophthalmic goitre were dealt with, and the suggestion was put forward that the difficulties might be due to a temporary immunity against the particular group required.

The following general conclusions were drawn: (1) Exophthalmic goitre was believed to be due to the excessive absorption of tryptophane from the intestine; this in turn was traceable to the absence of the indole producers from the intestine. (2) The absence of indican from the urine indicated the absence of indole producers from the intestine. (3) In exophthalmic goitre the early disappearance of indican from the urine was of serious prognostic importance. (4) Operative treatment had a definite place in the treatment of exophthalmic goitre. Medically, much could be done by suitable dietetic measures. (5) Diffuse parenchymatous goitre was characterized by an excess of indican in the urine, suggesting an excessive destruction of tryptophane. If this excess gave place to a diminution or complete disappearance of indican, that suggested that the case was assuming the exophthalmic form. (6) Myxoedema was due to atrophic changes in the thyroid gland, which lost its capacity for dealing with the circulating tryptophane, whether that substance was excessive, deficient, or normal in amount. Tho

disease was thus compatible with the presence or absence of urinary indican.

In the discussion which followed Dr. PRICHARD mentioned a case of exophthalmic goitre which improved very much after an attack of acute rheumatism. Professor E. J. MACLEAN mentioned the possible connexion between eclampsia and intestinal bacteria, and drew attention to the good results obtained by intestinal lavage. Dr. PARRY MORGAN mentioned the feasibility of influencing the flora by administering the required organisms in keratin capsules by the mouth.

Dr. H. A. HARRIS then gave a lantern demonstration of the cytology of tumours, illustrated in addition by numerous sections. The points of the differential diagnosis of benign, borderline, and malignant growths were presented. He further showed examples illustrating the presence of nucleolar fragments in the cytoplasm of mitosing cells in malignant tumours, a phenomenon confined to cancerous and sarcomatous growths, and hitherto undescribed.

Dr. J. W. TUDOR THOMAS presented a case of endothelioma of the orbit.

The patient was a young woman of 27, who gave a history of having had something wrong with the right eye since childhood, and that during the last two years the eye had become pushed forward. She complained of diplopia and occasional pain in the eye. A diagnosis was made of orbital tumour, probably a fibrosarcoma, and seven months ago the tumour was removed through an incision in the line of the eyebrow. It was firmly attached to the roof of the orbit, and appeared to be growing from the orbital periosteum, extending well behind the eye. The tumour was about the size and shape of a small pigeon's egg, and on microscopic examination was found to be an endothelioma. The patient now had no diplopia, and the eye gave her no trouble; it had returned to its normal place in the orbit, and was practically of similar appearance to the other eye.

### CHRONIC DUODENAL ILEUS.

A MEETING of the Midland Medical Society was held in the Medical Institute, Birmingham, on January 17th, with the President, Dr. PERSLOW, in the chair, when there were forty-five members present.

Mr. SKYMOUR BARLING read a paper on chronic duodenal ileus, and gave clinical histories of seven cases of the condition. In two of these the condition was caused by narrowing of the duodenal lumen by the invasion of the wall of the bowel by growth or inflammation, while the symptoms of the other five were due to obstruction at the crossing of the mesenteric root and the superior mesenteric vessels. After pointing out the similarity in the symptoms of these two groups of cases, the relationship of the condition to the etiology of acute gastro-duodenal ileus was considered. Diagnosis of the chronic condition could be made in a certain number of cases by a consideration of the clinical and radioscopic picture, but its mimicry of the symptoms produced by chronic appendicitis and gall stones and chronic duodenal and gastric ulcer was often very close. The disease must, he said, be regarded as a clinical entity to be considered whenever a case of chronic indigestion was being investigated, and when laparotomy was performed in such cases the routine examination should include the third part of the duodenum and the site of crossing of the vessels.

Mr. DINGLEY showed a specimen of the condition, which he had recently met with, and described two similar cases. Dr. T. L. HARDY described the results of gastric analysis by the fractional test meal method in some of Mr. Barling's cases. He stated that occasionally the diagnosis might be inferred from the chemical examination alone. Mr. BILLINGTON considered that the slighter degrees of the condition were not rare, and stated that in his opinion the mobility of the right kidney was occasionally responsible for it.

Mr. J. B. LEATHER showed a child of 12 years who had lost a considerable part of both hands and one foot as the result of syphilitic disease of the bone. Mr. SAMPSON said that he had seen similar loss of tissue as the result of obliterative endarteritis. Mr. ROSE thought that in this case Roynaud's disease could not be excluded.

Dr. A. P. THOMSON related the history of an obscure case of prolonged pyrexia, and showed a temperature chart (prepared in the manner suggested by Professor Arthur Hall of Sheffield) to illustrate the characteristics of the continued fever. The history was that of a previously healthy woman, aged 39, who eight months ago was seized with an illness which had since run a curiously intermittent course, corresponding with the intermissions of her temperature. While under observation in the hospital she had had bilateral effusion of blood in

both pleural cavities, and the spleen and liver for a time had been enlarged and hard. Physical examination and all ordinary clinical methods had yielded nothing on which to base a diagnosis. The most suggestive feature was the relapsing nature of the fever. Dr. Thomson thought that the case in all probability was one of Hodgkin's disease showing the Pel-Ebstein syndrome.

Dr. RUSSELL, for comparison showed a chart of a case of the Pel-Ebstein syndrome who had died under his care. Dr. ALFRED PINNEY mentioned that von Sieglar described two cases of undoubted Hodgkin's disease in which effusions of blood had occurred in the pleura and peritoneum, and he stated that in these cases it had been found that the effused blood showed a marked eosinophilia. Dr. NELSON considered that in spite of negative blood cultures septicaemia could not yet be excluded.

### DIET AND PREVENTIVE MEDICINE.

At a meeting of the Society of Medical Officers of Health held on January 19th, with the President, Dr. T. EUSFACE HILL, in the chair, a paper, followed by a discussion, was read by Professor E. MELLANBY of Sheffield University on diet as an important factor in preventive medicine.

After referring to the triumphs of preventive medicine in other directions he suggested that the study of diets might throw some light on the epidemiology of certain diseases not now well understood. Much of the food of the working classes was deficient in fat-soluble vitamins. They were not particularly fond of green vegetables, milk, cheese, or eggs. Their diet consisted largely of bread, butcher's meat, potatoes, margarine, jam, tea, and coffee. He urged that greater attention should be paid to pre-natal diet, and instanced an experiment he had made with a bitch who was deprived in the last month of pregnancy of fat-soluble vitamins. All the puppies died within eleven weeks of their birth. Deprivation during the whole of a second pregnancy was followed by abortion at eight weeks. In another pregnancy, when fed with cod-liver oil in addition to ordinary diet, she bore a litter of seven puppies, all of whom did well. The female, Professor Mellanby considered, had a great power of sacrificing her own tissues for the benefit of her offspring, but there must be a limit to this power, hence the importance of pre-natal diet. He was of opinion that the problem of defective teeth would be solved by greater attention being paid to the diet of children, and that the decline in infant mortality was largely due to the instruction in infant feeding which formed so large a part of infant welfare work. He concluded his paper by advising a greater consumption of cod-liver oil, which was the cheapest form of vitamins. Milk should form a larger part of our diet than was at present the case. The same advice applied to green vegetables, and especially raw salads. As a rule diets were rich in phosphorus but deficient in calcium, and the remedy might be found in the addition of about 2 per cent. of calcium carbonate to butter.

The PRESIDENT said that his experience in the county of Durham was that the number of rickety children had considerably decreased since the introduction of dried milk. In view of the importance attached to calcium it would be valuable to know whether in areas where the water supply was rich in that mineral that fact counterbalanced the butter deficiency in it.

Dr. JAMES WHEATLEY considered that researches into the influence of diet were among the most important means of improving the health of the nation, as well as the easiest. Pressure should be brought on the Government with a view to suitable propaganda. Professor Mellanby's researches once again emphasized the value of cod-liver oil and milk at welfare centres. Dr. E. H. T. NASH raised the question of the purity of cheap cod-liver oil; he was informed that on many fishing boats the crews added the livers of herrings and other fish to the liver baskets.

Dr. W. J. HOWARTH asked whether the reduction of infant mortality was due to pasteurization or dried milk. Cod-liver oil had been regarded almost as a specific for tuberculosis and such cases benefited also by milk, butter, and sunshine. From a farming experiment he had carried out he got striking results by feeding the sow in pig with cod-liver oil, milk, yeast, lemons, etc. The young at birth were in excellent condition, and when the litter was disposed of they were about three weeks in advance of others of the same age as a marketable commodity. He inquired whether there was any truth in the statement sometimes made that the refining of cod-liver oil resulted in its deterioration as a foodstuff.

A MEETING of the Bath Clinical Society was held on January 5th at the Royal United Hospital, with Mr. MUMFORD, the President, in the chair. Mr. F. FRASER showed: (1) A case of old osteomyelitis in which the growth of the tibia had ceased, with the result that the tibia had outgrown and distorted the leg considerably; the orthopaedic proceedings necessary to correct the deformity were described. (2) A child sent in as an "acute abdomen" and proved to be a case of double pneumonia and of acute pneumococcal peritonitis, with complete recovery. (3) A case and specimen of abdomino-perineal removal of the rectum and sigmoid. The patient a month after the operation was remarkably well. Dr. R. G. GORDON showed a case of malignant disease of the right testicle growing up the canal. Mr. A. L. FULLER showed a specimen of a left broad ligament dermoid with torsion of the omentum and separation of the tumour from the uterus by torsion. Dr. W. P. KENNEDY showed an x-ray plate of the cervical spine showing fracture of the body of the third cervical vertebra. Dr. V. COATES showed a plate of the sella turcica in a case of acromegaly. Dr. R. G. GORDON showed a photograph and radiogram of nodes in an early case of rheumatoid arthritis. Dr. RAY EDRIE read a paper entitled "Romance and the pharmacopoeia," dealing particularly with the career of Dr. Thomas Dover (1660-1742), famous for his powder and notorious for his piracy on the Spanish Main (see BRITISH MEDICAL JOURNAL, February 18th, 1922, p. 280).

ON January 24th Sir DYCE DUCKWORTH delivered an address to the Cambridge University Medical Society on "The essential equipments for the best pursuits of modern medicine." Sir Dyce Duckworth referred to the ever-increasing number of years which the modern student must devote to securing an adequate knowledge for ordinary practice. The best physicians, he said, were those who had cultivated breadth of mind, and this was most easily attained from a comprehensive classical or mathematical preliminary education. The perfect practice of medicine consisted of science and art, but the combination of these two received inadequate emphasis in lectures and at the bedside. Sir Dyce Duckworth then discussed some of the recent discoveries of modern medicine—in particular, vaccine treatment of various morbid conditions—and suggested that the student would do well not to accept such novelties too hastily. Those who knew French or German, and had an opportunity of spending some time at Continental or American clinics, were very fortunate. In his concluding remarks the lecturer said that the best practitioners were certainly those who regarded their profession as a noble and honourable one, and strove on all occasions to take a high line of conduct in their duties, however humble their patients might be.

## Reviews.

### COLLOID CHEMISTRY.

THE pursuit of knowledge in the realm of colloid chemistry has gained fresh impetus from the publication of LOEB'S *Proteins and the Theory of Colloidal Behaviour*.<sup>1</sup> The book is founded on Loeb's own experimental work, which has led to conclusions that would explain in a very simple manner a number of forms of colloid behaviour which have hitherto remained a source of perplexity or have been accounted for by far-sought explanations. He considers that in the experimental work of other investigators there has been a tendency to neglect the effects of hydrogen ion concentration in the liquids subjected to experiment, and he has sought methods by which the effect of this factor could be controlled. They led him to the conclusion that the combination of proteins with acids and bases is fully obedient to stoichiometrical laws. This paved the way to the further conclusion that only the valency of the ion and its sign of charge participate in determining the physical properties characteristic of colloids. Loeb accordingly interpreted the experiments of Ostwald and Fischer differently from Zsigmondy. Their experiments on the relative efficiency of different ions were made without regard to hydrogen ion concentration. Hence, Loeb argues, Ostwald's experiments only proved that acetic and boric acids are weaker acids than nitric, and not that the acetate and borate anions have a greater depressing effect on the swelling of gelatin than the nitrate anion. Similarly Fischer's work, he thinks, only proved that citrates and acetates are buffer

salts, not that the acetate and citrate anions have a greater depressing effect on the swelling of gelatin than the chloride and nitrate anions.

Loeb entertained as possible the hypothesis that the behaviour of proteins under the influence of electrolytes might be explained by Donnan's theory of membrane equilibrium. His work having been specifically directed to test this view, Loeb has attacked the problem of colloidal substances from a new standpoint. His results appear to lead to the conclusion that two data of classical chemistry suffice to explain colloidal behaviour both qualitatively and quantitatively; these are the stoichiometrical law and Donnan's theory. The text of the volume contains the evidence for this view. The swelling of gelatin is explained simply by the consideration that the forces of cohesion between the gelatin molecules produce the conditions of a liquid enclosed by a surface which acts as a membrane boundary exhibiting the Donnan effect. The potential differences demanded by the Donnan theory, vainly sought by Ehrenberg, have, Loeb contends, now been found. A full account is given of the author's experimental, work beginning with the preparation of proteins free from ionogenic impurities. The methods adopted show no defects in principle, and the tabulated results agree with the demands of theory. Further, it was found that what had been done with gelatin could be repeated point for point with crystalline egg albumen and other proteins. If this be accepted, then the adsorption theory, the aggregate theory, and the hydration theory become unnecessary, and the Hofmeister ion series loses all validity.

Loeb holds that the suggestion that the laws of classical chemistry must be replaced by other laws peculiar to colloid chemistry has no foundation, and claims to have succeeded not only in satisfying the postulates arising from his own views but to have adduced experimental confirmation of the falsity of views conflicting with his own. The manner in which he writes compels trust in the author's experimental work. While advocating his conclusions in a convincing manner, his discussion of subjects which admit of controversy is both temperate and fair. Having regard to the radical character of the conclusions reached, it is hardly to be expected that they will be accepted by everyone without demur. They will doubtless be submitted to searching criticism, both reasoned and experimental; but unless the author has erred fundamentally the work will mark a distinct stage in the progress of knowledge in this realm of study.

Sir WILLIAM BAYLISS, in his book, *The Colloidal State in its Medical and Physiological Aspects*,<sup>2</sup> gives a very clear and concise account of those features of colloidal chemistry which are of particular interest in medicine and physiology. Colloidal chemistry is a difficult subject because many of the fundamental principles are still matters of dispute, and unfortunately those problems which are of chief interest in physiology happen to be the most complex and obscure portion of the subject.

Sir William Bayliss states the salient facts as simply and as shortly as possible, and readers will be agreeably surprised to discover how much of colloidal chemistry can be explained without the aid of an extensive special terminology, and also without the use of mathematical formulae. He pays considerable attention to the properties of protein solutions, and it is interesting to note that he does not accept a large proportion of the theories recently expounded by Loeb.

Loeb's book reviewed above has attracted a good deal of attention. In his view the behaviour of proteins can be explained by ordinary chemical laws, so that there is no need to accept the occurrence of such special processes as adsorption, etc., which most workers have found it necessary to assume in order to explain their results. This, if true, would result in a very great simplification of the whole subject. Bayliss, however, considers that the theory is still not proven, and states:

"The work of Loeb has undoubtedly brought to light many important facts under the particular conditions of his experiments, but there are reasons for doubt as to whether all the properties of proteins can be explained by combinations with acids or bases in equivalent proportion, apart from changes in physical state or adsorption."

The whole subject of colloidal chemistry is fascinating, and since the animal body is composed of colloidal solutions, it

<sup>1</sup> *Proteins and the Theory of Colloidal Behaviour*. By J. Loeb, member of the Medical Research, New York. London: 1922. (Demy 8vo, pp. xi + 232. 15s. net.)

<sup>2</sup> *The Colloidal State in its Medical and Physiological Aspects*. By Sir William M. Bayliss, F.R.S., Publications, London: Henry Frowde, pp. 95; 12 figures. 6s. net.)

a knowledge of the special laws governing colloidal reactions is essential for the understanding of physiological processes. The subject is, however, comparatively new and has been veiled from the common view by a complex terminology and the extensive use of mathematical formulae. As a result, there has been a tendency to regard colloids as something rather mysterious. This book by Sir William Bayliss appears therefore very opportunely. Anyone with a slight knowledge of general chemistry can understand the arguments, and can learn what are colloids, and what are their chief special properties. It is to be hoped that the book will be read widely by medical men; from it they will learn that when a drug is prepared in the colloidal state it does not necessarily acquire any special therapeutic qualities.

### FOOD, HEALTH, AND GROWTH.

We welcome the introduction into this country of the little volume, *Food, Health, and Growth: A Discussion of the Nutrition of Children*, in which the Lane lectures, delivered by Dr. Emmett Holt, at the Medical School of the Leland Stanford Junior University, in San Francisco, in December, 1920, are reproduced. Although the title might well have been "Food in relation to health and growth," for it is almost exclusively devoted to food considerations, its designation will probably attract many readers. This is most fortunate, for a considered and authoritative pronouncement on food questions is greatly needed at the present moment, owing to the tendency among the lay public, and, indeed, among members of our own profession, to lose all sense of proportion in appraising food values since the new discoveries in relation to the accessory factors have brought the vitamins into so much prominence.

Dr. Holt's eminently sober judgement on these matters will help to restore equilibrium and to assign to each food factor, whether primary or accessory, its due place in the economy of nutrition. A very considerable share of the available space is devoted to questions of quantity as measured in calories—the only possible units in which quantities can be expressed accurately. It is all the more regrettable that in the appendix at the end of the book the tables of calorie values are so badly arranged and inaccurate. In some cases these values are given for ounces of food, in others for slices (ginger bread, sponge cakes, etc.), in others in spoonfuls (butter, sugar, etc.), and yet in others in such undetermined measures as sticks (celery) or leaves (lettuce).

Dr. Holt emphasizes very strongly the large calorie requirements of boys and girls at or about the time of puberty, but he appears greatly to exaggerate their needs, and to place too much reliance on Rubner's unsubstantiated formula, which requires 500 calories for growth in the 16th year of life, during which there is an average increase in weight of about 14 lb. This means that to secure this small increment in bodily weight about 650 lb. of solid meat must be consumed, a very extravagant allowance. There can be no doubt that the large appetite of boys at this age has a physiological basis, but it may represent a demand for some food, and not for an energy-producing food, which could be more economically supplied without having to rely on the large consumption of foods in which the required element or elements is poorly represented.

The author pays considerable attention to the connexion which certainly exists between nervous symptoms and under-nourishment; he perhaps rather exaggerates the relation of mental defect to underfeeding; he says, "When large groups are considered feeble mental capacity goes with small bodies," and although he supplies substantial evidence in favour of the view that good nutrition is an essential for the best school work, in claiming that mental defect and incapacity are due to bad nutrition he may be putting the cart before the horse, or confusing causes and effects.

It is noticeable that in his very full account of the factors which are essential for good nutrition Dr. Holt pays so little attention to considerations of digestion or to the conditions of malnutrition which may result from food which, otherwise blameless as regards calorie value, balance, and vitamin content, is incapable of adequate digestion. The quality of digestibility is at least of equal moment with a correct balance.

In a book so excellent and free from blemishes the reviewer is grateful to find even one in Dr. Emmett Holt's

position open to criticism, for excess of praise is no recommendation. We strongly advise all those who wish to acquaint themselves with the present position of knowledge with regard to food and nutrition to purchase this little book and to read it carefully.

### THE ART OF SPEAKING AND SINGING.

CONVICTION is the goal of the speaker. Gabbling, mouthing, ranting, drawling, affectation, or sing-song cannot be convincing; the idea to be expressed must first of all be made part of the speaker, and in its expression every movement must be so controlled that it exactly harmonizes with the idea. Dr. H. H. HULBERT has written a book entitled *Eurhythm: Thought in Action*, and in it expounds the principles of controlled expression, and the means whereby this art may be cultivated. The theories he advances are the outcome of practical work carried on for years in connexion with the vocal therapy of London County Council teachers, and during the war in connexion with the physical therapy of injured soldiers. His book was begun in 1911, and finished in 1921, so that every point has been carefully thought out, well deliberated upon, and carefully expressed. In successive chapters the author deals with self-control, discipline in games, the poise of the body, the appreciation of the beautiful, the art of expression, and then develops his thesis in the more detailed examination of the central apparatus of speech, the sounds of the English language, breathing in voice production, and the general hygiene of voice-users. Finally, a number of exercises for the practice of eurhythm are given. Dr. Hulbert rightly calls attention to the heavy work of teachers in voice usage, and the frequency with which this has to be done under unsatisfactory conditions. The voice-user's arch-enemy is noise; bad discipline in the classroom, traffic outside, reverberations through ill constructed floors, all make the task of the teacher unnecessarily heavy and increase the liability to breakdown. The chapter on "Hygiene for voice-users and ordinary health exercises" is excellent, and good scientific common sense. It is possible that some may argue that the attention which the author has given to physiological processes has made the book unduly long for his purpose in view, which is the instruction of the layman who is a voice-user; but if his effort secures due respect for that most human of attributes, intelligent speech, then there is not a word too much. The book is well illustrated and arranged.

### INTOXICATIONS: DEFICIENCY DISEASES.

THE twenty-second volume of the *Traité de pathologie médicale et de thérapeutique appliquée*, edited by Professor E. SERGENT and Drs. L. RIBADEAU-DUMAS and L. BABONNEIX, deals with intoxications, deficiency diseases (*maladies par carence*), injuries by physical agents, and the effects of injuries upon diseases. The textbook is well illustrated, the printing is good, and the articles as a whole are written in a clear and readable style, such as one usually finds in French scientific literature.

The chief articles are those upon drug habits by Dr. Legrain and the article upon deficiency diseases by Professor Mouriquand. Dr. Legrain writes eloquently and at length (169 pages) on the evils of alcoholism. He deals very fully with its effects upon the reproductive organs, and upon offspring. He has examined the voluminous literature, and gives a good summary of the case against alcohol. The evil effects produced upon the offspring when either parent is under the influence of alcohol at the time of conception are vividly described. The psychological changes produced by alcohol are described at length, and the stages of intoxication and subjective feeling at the various stages of intoxication are detailed. We are surprised, however, that no reference is made to the numerous researches that have been conducted to analyse the effect of alcohol upon psychological reactions. Similarly nothing is said upon the action of alcohol as a food, or upon the effect of alcohol on the functions of digestion, respiration, and circulation. The article would have been improved if more space had been devoted to a consideration of the ascertained facts about the action of alcohol upon the body, and space for this could profitably have been

<sup>1</sup> *Eurhythm: Thought in Action*. The Principles and Practice of Vocal and Physical Therapy. By H. H. Hulbert, M.A., Oxford, M.R.C.S., L.R.C.P., etc. London: Novello and Co., Ltd. 1922. (Sup. roy. 8vo, pp. 159; 45 figures, 9s. net.)  
<sup>2</sup> *Traité de pathologie médicale et de thérapeutique appliquée*. Published under the direction of E. Sergent, L. Ribadeau-Dumas, and L. Babonneix. Tome xxii. Intoxications. Paris: A. Maloine et Fils. 1922. (Demy 8vo, pp. 553; 31 figures, 2 coloured plates. Fr. 28.)

<sup>3</sup> *Food, Health, and Growth: A Discussion of the Nutrition of Children*. By J. Emmett Holt, M.D., LL.D. New York: The Macmillan Co. 1922. (Cr. 8vo, pp. viii + 273; 21 figures. 7s. 6d. net.)

obtained by omitting some of the eloquent descriptions of the evils of alcoholism, which, although true, would seem to be more suited for prohibitionist propaganda than for a scientific textbook. The articles upon etherism, morphinism, and cocaineism, by the same writer, are open to the same criticism that too little definite information is given as to the exact effects upon the mind and body which abuse of the drugs produces.

Professor G. Mouriquand has written seventy pages upon *Les maladies par carence*. The term is a comparatively new one, and under this heading are included the diseases which are produced by a deficiency in the diet of some constituent essential to health. The chief diseases described are beri beri, pellagra, and scurvy; the full account given of these diseases is supplemented by some very good illustrations. The author classifies *Les maladies par carence* as follows:

1. Diseases due to chemical deficiency (*carence chimique*), which include diseases due to the following causes: (a) vitamin lack—for example, beri-beri, xerophthalmia, and perhaps rickets; (b) lack of amino-acids (for example, pellagra), lack of essential mineral salts, and lack of essential metals; (c) lack of carbohydrates and fats.

2. Diseases due to physical deficiency (*carence physique*). This deficiency is stated to be due to some alteration in the food, caused by sterilization or desiccation, producing some important change in its molecular texture. Scurvy is described as a disease of this type.

This classification is to be commended in that it associates diseases due to vitamin lack with the other types of deficiency diseases. The author's views upon the causation of scurvy, however, differ from those commonly accepted in this country. Under the heading "Avitaminose C" he merely states, "Vitamin C is absolutely hypothetical. It would represent, as we have seen, in the mind of certain authors the antiscorbutic vitamin. Nothing has been less proved. Scurvy is above all things—for the present at least—a lack of fresh food [*carence de l'aliment frais*], and it is not possible to give a more exact definition."

These sweeping statements appear very difficult to justify. Scurvy is not simply due to lack of fresh food, since it can be prevented or cured by the juice of citrus fruit which has been preserved for more than a year. The usual view is that the antiscorbutic vitamin is an unstable substance which is very easily oxidized. This belief is supported by a large volume of evidence, and there seems no valid reason to assume that the change which destroys the antiscorbutic value of food substances is of a physical rather than of a chemical nature.

In addition to the articles already mentioned there are numerous others of interest in the book, in particular that by Professor Chiray upon local internal disorders revealed or aggravated by injuries; it gives a clear account of the medico-legal problem of the influence of injuries upon the development of diseases such as tubercle of the joints, etc.

## NOTES ON BOOKS.

THE volume of *Persian Sketches*,<sup>6</sup> by the Anglican Bishop in that country, consists of short descriptions of life on the road, and in the villages and towns, written with a genial humour which withstands even a very thorough looting by highwaymen of the caravan with which he was travelling. We have entertaining accounts of the muleteer and the servant, and of their special brand of honesty, of the merchant and of the hakim, whose profession was, until recent tendencies produced some changes, usually hereditary; the old hakim seems still much in the stage of Master John Arderne, but without his surgical enterprise. A Government medical college now exists in Teheran, and it is, the author says, becoming difficult for a Persian to get a licence to practise unless he possesses the diploma of that college or some recognized qualification. All the new doctors, it would seem, should find plenty to do, for venereal diseases are rife, tuberculosis is making extraordinarily rapid progress, "especially among nomads," opium smoking is becoming very common, and child marriage is the rule, though a public opinion against it is growing. The conditions of child labour in the carpet factories have been terribly bad, but there is a promise that ventilation shall be improved and overcrowding diminished, that the minimum age of workers shall be 8 for

boys and 10 for girls, and that no child under 14 shall work more than eight hours a day. Bishop LINTON is sympathetic towards the Persian, recognizes his good qualities, reminds us of some of our own industrial shortcomings, which we began to remedy less than a century ago, and demands that we shall not pass the Persian by, pharisaically, on the other side. Sir PERCY SYKES has written a short preface in which he says that Persia is at the parting of the ways, and that she can only find the right road if the grandees reform themselves, renounce their privileges and pensions, and get rid of their hordes of idle retainers. He praises the missionary effort, British and American, especially the schools, but does not minimize the change that must come over the mind of the Persians if their country is to be saved from ruin.

Dr. MAURICE LETULLE's book on the physical examination of the chest and abdomen, first published in 1913, has recently reached its third edition. It is a very full and practical handbook,<sup>7</sup> differing from other works of the same kind chiefly by the free use of skiagrams, which are explained by diagrams on the opposite page. It contains also a number of sketches illustrating the relative positions of the physician, and patient. The British reader will be struck by the large amount of space given to immediate auscultation of the lungs and the heart, with the physician's head on the patient's chest, and by the summary way in which the binaural stethoscope is dismissed; all the illustrations of mediate auscultation show the wooden stethoscope in use; it is merely said that flexible stethoscopes, "single, or even binaural," are sometimes used.

A review of the first edition of the book by Professor ZINSSER of Cologne on syphilis and syphilis-like diseases of the mouth<sup>8</sup> appeared in these columns ten years ago, and shortly afterwards a notice of the English translation. A third edition has now been produced. As before, there are chapters describing syphilis primary, secondary, tertiary, and congenital, and two more chapters devoted to the differential diagnosis of secondary and tertiary syphilis of the mouth. Attention was called to Professor Zinsser's views on syphilitic affections of the teeth on a previous occasion. The great feature of the book is the atlas, chiefly of coloured plates, the number of which has been increased in this edition; they include lifelike representations of every kind of syphilitic affection of the lips, teeth, palate, tongue, and fauces. There are also coloured plates showing every disease of the mouth which could possibly be mistaken for syphilis. This should make the book of interest to all, but particularly to dentists, to whom these conditions are of special importance.

Professor OTTO FOLIN, who holds the chair of biological chemistry in Harvard Medical School, has issued a third edition of his *Laboratory Manual of Biological Chemistry*.<sup>9</sup> It was prepared for the use of medical students in that school. The text is printed on one side of the paper only, so that notes can be made on the other page. The new edition has been revised and many new methods introduced.

<sup>7</sup> *Inspection-Palpation, Percussion, Auscultation: Leur Pratique en Clinique médicale*. By Maurice Letulle. Third edition. Paris: Masson et Cie. 1922. (Crown 8vo, pp. 344; 133 figures, 12 plates. Fr. 14 net.)

<sup>8</sup> *Syphilitische und syphilisähnliche Erkrankungen des Mundes. Für Ärzte, Zahnärzte und Studierende*. Von Dr. Ferd. Zinsser. Dritte erweiterte Auflage. Berlin and Vienna: Urban und Schwarzenberg. 1922. (Sup. roy. 8vo, pp. viii + 134; 71 plates. The price should be ascertained from a bookseller.)

<sup>9</sup> *Laboratory Manual of Biological Chemistry*. By Otto Folin. Third edition. London and New York: D. Appleton and Company. 1922 (Demy 8vo, pp. ix + 309; 7 figures. 12s. 6s.)

## MEDICAL AND SURGICAL APPLIANCES.

### An Aris-Traction Lever.

DR. E. W. FARMER (Levensham) writes: Having on several occasions had reason to be dissatisfied with Le Page's tractor because of its insecure hold on the

midwifery forceps, I designed one which appeared to me to be likely to secure a better hold, and to be easier of application. The force is exerted on the shanks of the forceps, not on the handles, so that the leverage is in the more correct axis,

and the instrument is consequently more efficient. Messrs. Mayer and Phelps, of New Cavendish Street, have made from my model an instrument which I have had occasion to put to practical use; it answers my expectations in every way.

<sup>6</sup> *Persian Sketches*. By the Right Rev. J. H. Linton, D.D. With a foreword by Brigadier-General Sir Percy Sykes, K.C.I.E., C.B., C.M.G. London: Church Missionary Society. 1923. (Post 8vo, pp. viii + 139; illustrated. 2s. 6d.)

## THE MAUDSLEY HOSPITAL.

## OPENING CEREMONY.

The Maudsley Hospital was formally opened on January 31st by the Minister of Health, Sir Arthur Griffith-Boscawen, who was received by Mr. Francis R. Anderton, chairman of the London County Council; Mr. David Cawdron, chairman of the Mental Hospitals Committee; Mr. E. Sanger, chairman of the Maudsley Hospital Subcommittee; Sir Frederick Mott, director of the Pathological Laboratory; and Dr. E. Mapother, superintendent of the Maudsley Hospital. Mr. Cawdron gave a short review of the history of the hospital and described the functions it was designed to fulfil. After the Minister of Health had declared the hospital open he made a tour of the building, visiting the out-patients' rooms, the rooms reserved for the use of private patients, the wards of the hospital, the garden, the nurses' home, and the pathological laboratory.

The hospital has been erected on a site at Denmark Hill, four and a half acres in extent, opposite King's College Hospital; the pathological laboratories and the administrative offices are in the front, the wards in a lengthy building at a right angle to the main block. The wards and corridors are airy and well lit, and the designers of the hospital have been successful in getting rid of any suspicion of "asylum" atmosphere. Each ward consists of a dormitory, sitting-room, and dining-room, and in the lower wards the beds can be wheeled out on to commodious verandahs; there is ample locker accommodation—the patients wear their own clothes—and special provision is made for treatment by continuous baths, which have been found beneficial in early cases of mental disorder. Each ward has a small library and a piano, there is an abundance of comfortable chairs, brightly coloured cushions, and cheerful hangings, and the many pictures throughout the institution have been chosen with unusually good taste.

The Maudsley Hospital is the first institution to be established in this country on the lines of the neurological and psychiatric clinics of the Continent and America, which are designed for the combined treatment and investigation of organic nervous disease, neuroses, and incipient psychoses. It represents the first provision made by a public body in England for the treatment of early and recoverable types of mental disorder entirely on a voluntary basis and apart from certified cases. The London County Council did not take this step on its own initiative. It was stimulated by the urgent representations of the late Dr. Henry Maudsley, who backed his opinion by making during his lifetime a donation of £30,000 towards the cost of building, and left a further £10,000 by his will for the purposes of the hospital. The hospital bears the name of Dr. Maudsley, and its foundation was made possible through his generous gifts, but it is allowable to doubt whether Dr. Maudsley's scheme would ever have been realized but for the untiring perseverance, in face of much discouragement, of Sir Frederick Mott; it was through him that Dr. Maudsley, some fifteen years ago, made his offer to the London County Council, but there was much delay, largely unexplained and not altogether creditable to the County Council, in finding a site and building the hospital.

By slow degrees, however, the project advanced, but the building was still unfinished at the outbreak of war. In 1915 the War Office approached Sir Frederick Mott, who was in charge of the neurological department of the 4th London General Hospital, and the erection of the Maudsley Hospital was then soon finished by the London County Council; it was taken over by the War Office in 1916 as a neurological hospital. The pathological laboratory of the London county mental hospitals was transferred from Claybury to the Maudsley Hospital, and, both during the war and since, the routine and research pathological work of the mental hospitals has been carried on there. During the war many distinguished foreign neurologists, including Professor Marinescu of Bucarest, worked in the laboratory. After the war the Ministry of Pensions occupied the hospital for some eighteen months, and since the Ministry gave it up it has remained empty until the present.

The hospital buildings have been renovated and completely furnished, and now await patients. There is an out-patient department, where a fee of 2s. is charged for each attendance; this may be remitted wholly or partly if the patient cannot afford it. The accommodation for in-patients is of two kinds; there are six wards, containing a total of 144 beds—72 for each sex—in dormitories and separate rooms; there are also thirteen private rooms for female patients, a special dining-

room, sitting-room, and garden being associated with these rooms, for which an inclusive charge of 6 to 7 guineas a week is made. Patients with a legal settlement in the county of London are required to contribute according to means, while those without such legal settlement cannot be received into the hospital unless they are prepared to pay the full maintenance rate of £5 a week.

In making his gift Dr. Henry Maudsley had three main objects: The early treatment of cases of mental disorder; the promotion of exact scientific research into the causes and pathology of mental disorder, with the hope that much might yet be done for its prevention and successful treatment; and the provision of an educational institution in which the best clinical instruction should be available. Dr. Maudsley believed that the establishment of such a hospital in London was vital because of the association it could have there with the university, the general hospitals, and the medical schools. The study of insanity has, up to the present, remained to a great extent an isolated branch of medical research, and it was believed that if this defect were remedied a closer acquaintance with the peculiarities of mental and nervous diseases would become more common, and many cases which now find their way to the workhouse or the asylum would recover, under suitable treatment, without needing confinement in an institution.

The treatment of the nervous and psychological cases to be admitted to the Maudsley Hospital will be under the control of the medical staff, which consists of the superintendent, Dr. Edward Mapother, and four whole-time medical officers; with the voluntary help of a considerable number of qualified medical men and women as clinical assistants. There will thus be ample provision for the detailed investigation which is the foundation of any adequate treatment of mental or nervous disorder. Such investigation will be greatly facilitated by the fact that the hospital is associated with the pathological department of the London county mental hospitals, under the direction of Sir Frederick Mott. The services of consultant specialists will be available for patients suffering from surgical, gynaecological, and obstetrical conditions, and disorders of the eye, ear, nose, and throat; a dental surgeon will also attend. Particular care has been devoted to the selection of the nursing staff, which consists of a matron, an assistant matron, seven sisters, eighteen nurses, twenty-one probationers, and twelve male nurses; all the nursing staff, except the probationers, possess a certificate of general hospital training for at least three years at a nursing school; the nursing of the male patients will be carried out almost entirely by women.

Treatment as an in-patient will be entirely on a voluntary basis; every patient before admission will be required to sign a formal application which will intimate his right to leave the hospital within twenty-four hours of giving notice of his desire to do so. No patient will be admitted under certificate or will be certified in the hospital either for retention there or for transfer to a mental hospital elsewhere. Given the essential willingness to undergo treatment, good prognosis as to recovery is the main feature constituting the suitability of cases for admission. In fact, cases without such a prognosis will be admitted only on account of difficulty of diagnosis or exceptional scientific interest.

It should, however, be realized that while the provision of the Maudsley Hospital marks a great advance, yet the present laws as to the treatment of mental disorders prevent full advantage being taken of it. Admission as an in-patient is restricted at present to those able and willing to sign a formal application to be admitted to the hospital for treatment. Cases from such temporary mental conditions as acute delirium or puerperal fever cannot express in writing a desire for treatment, and are therefore debarred from entering the Maudsley Hospital as in-patients; similarly with children, those suffering from adolescent mental disorder cannot be received for treatment, simply because they cannot express in writing a desire to be so treated. As cases under certificate are not to be received, this also means the exclusion of some cases of the most suitable class for teaching and for treatment to recovery, and until there is a reform in the law providing for reception, without certification, of certifiable cases, subject to proper safeguards, the work of the hospital will be seriously hampered. Perhaps the experience which is to be gained at the Maudsley Hospital may hasten the legislation that is urgently required in order to give those afflicted persons who are in the early stages of mental disorder the benefit of modern advances in psychiatry.

## British Medical Journal.

SATURDAY, FEBRUARY 3RD, 1923.

### MICROBIAL TRANSMISSIBLE AUTOLYSIS.

THE phenomenon of the sudden dissolution of bacteria when brought into contact with tissue fluids would probably not have attracted attention outside the narrow circle of those whose business it is to study bacterial activities but for the dramatic theory propounded by Dr. d'Herelle, of the Pasteur Institute, to explain this rapid destruction of bacterial cells. He claimed to have discovered the existence of ultramicroscopic parasites of bacteria, and suggested therefore that these organisms, hitherto considered to be amongst the lowliest forms of life, are preyed upon by even lowlier forms, and become the victims of infective forces which invade and dissolve the cells. Not only was this idea foreign to current conceptions of bacterial existence, but it also postulated the existence of hitherto undescribed manifestations of life, and therefore made the problem of bacteriolysis of interest to all biologists. Thus a simple observation of factors influencing the metabolism of bacteria, such as is frequently recorded in bacteriological literature and rarely penetrates beyond the seclusion of the laboratory, has been brought to the notice of all branches of science and has been led unexpectedly into the arena of world-wide controversy.

The whole question was debated at length at the Microbiology Section of the British Medical Association meeting at Glasgow, and the opening papers and subsequent discussion were printed in full in this JOURNAL. At that meeting we were fortunate in having present both Dr. d'Herelle, who came over especially from Paris, and also Dr. Twort of the Brown Institution, as well as other laboratory workers from the Continent and from this country who have been devoting themselves to the study of this difficult problem. It became obvious at that meeting that more extensive research would be necessary before any definite opinion could be formed as to the validity of any particular theory, and until we are equipped with more accurate knowledge judgement must be reserved. But though no altogether satisfactory explanation has yet been adduced, the facts of the case are beyond dispute and have been verified by numerous investigators.

In his studies on filter-passing viruses Dr. Twort noticed a peculiar change in appearance of the colonies on agar of a micrococcus recovered from calf lymph, so that some colonies assumed a glassy or transparent aspect; this change began as clear spots at the margins of the colonies. Films made from such colonies showed that the organism had lost its characteristic morphology and nothing but small granules could be detected; moreover, subcultures from such altered colonies often failed to develop. It was obvious that some change had taken place, and, though Dr. Twort hesitated to give any confident interpretation of the phenomenon, he suggested at the time that it might be due to "an acute infectious disease of micrococci." This pronouncement, however, did not arrest attention outside technical circles, and his observations, in so far as they concerned this particular phenomenon, passed practically unnoticed. Interest was reawakened by the researches of Dr. d'Herelle two years later. He filtered a watery suspension of faeces from a case of dysentery through a porcelain filter and observed that a drop of this bacterial filtrate when added to a broth culture of the dysentery

bacillus (Shiga) causes the turbidity to disappear, and on examination it was found that a very large number of the bacteria had been dissolved. Then he observed that a drop from this lysed culture added to another broth culture of the same organism induced a like change in this, and a drop from the second culture produced the same result in a third, and so on indefinitely. Obviously the lytic agent had multiplied, since the drop added, for instance, to the tenth tube of the series represented but a minute fraction of the original drop from the filtrate, but it yet induced the same change with equal rapidity. Dr. d'Herelle thereupon declared that these results could only be explained on the supposition that the lytic principle was a living agent, and, since this lytic property was possessed by filtrates, and such fluids revealed no living cells by microscopic examination, he propounded the theory that bacteria might become parasitized by ultra-microscopic filtrable viruses which attacked them, and multiplied within their cytoplasm, so that the cells ruptured and were dissolved. He named the infective agent "the bacteriophage." D'Herelle has defended his hypothesis against considerable opposition, and has within the last three years amassed a volume of experimental evidence in support of his views.

Professor Bordet, the director of the Pasteur Institute at Brussels, whose researches in kindred problems have given him a world-wide reputation, quickly brought his critical faculties to bear on this important theme, and found himself at variance with the doctrine of the bacteriophage. He injected the colon bacillus into the peritoneal cavity of a guinea-pig, and, a few days after the last injection, collected a few drops of the leucocytic exudate by puncturing the abdominal cavity; he found that this exudate might be capable of inducing the transmissible lytic property when mixed with a trace of a culture of the colon bacillus. But this experiment did not always succeed, and, although it has often been found that pus is endowed with lytic properties, it was not possible to explain the phenomenon as due to a ferment secreted by the leucocytes. The explanation offered by Dr. Bordet in his recent Cameron lecture in Edinburgh, which we publish to-day, attributes the lytic phenomenon, not to the agency of an invisible parasite, but to a process of transmissible autolysis which is a direct consequence of a "nutritive vitiation of the bacterial metabolism, primarily induced by some external disturbing influence." This vitiation results in the production of a lytic chemical principle capable of communicating the same vitiation to new microbes belonging to the same species when brought into contact with them. The bacteria thus affected are not immediately destroyed, but are still capable of multiplying before they undergo the lytic process, and so of reproducing the lytic substance. Some disturbing influence is necessary to cause this nutritive vitiation of the bacterium in the first place; but, after the appearance of the lytic agent, no interference is necessary, since the reproduction of the principle requires only the presence of living microbes which, having absorbed a sufficient quantity of it, liberate fresh quantities of the same agent at a certain stage of their evolution. Some cells become more and more resistant to the action of the lytic principle, and it may be that the transmissible autolysis is evolved for the benefit of the species, so as to favour the development of more hardy strains, and that it actively contributes to the appearance of new races of the microbe and allows the phenomenon of mutation to be more readily elicited. It certainly would assist us to understand this remarkable behaviour of bacteria if there were proof that some advantage was gained by the cells which suffered these disturbances.

Professor Bordet's general review of the subject shows clearly that the various facts observed can be explained

as readily (if not more readily) by the theory of transmissible autolysis as by the postulation of the bacteriophage. It was pointed out during the discussion on this subject at Glasgow that we ought to hesitate before entertaining any theory which is "contrary to the naturalness or likelihood of things," and this conservative attitude makes us incline more to the explanations of Bordet than to the doctrines of d'Horelle. Other theories have also been advanced to explain the bacteriolysis, but none of them have found so many adherents as the two we have considered here. It would be well if all the champions of different theories observed the same moderation, the same restraint, and a similar diffidence to that exhibited in this scholarly review by Bordet. We note that the theory of transmissible autolysis is put forward as the one which the author deems to be the most probable, but he admits it still lacks indisputable demonstration. It will serve as a working hypothesis, and until further knowledge is gained it will act as a guiding principle in research.

### GALEN.

ONE wonders whether any man's fate has been so strange as that of Galen. He made no overwhelmingly great impression upon his contemporaries, but that has been the fate of many literary giants; a thousand years after his death his influence was enormous, and that, again, has happened to others. But nearly two thousand years after his death his fame has almost evaporated, and in this he is exceptional; a circle of readers won with difficulty is usually not broken. Aristotle can count on some thousands of readers, Hippocrates upon some hundreds, Celsus on at least as many; but no complete text of Galen has even been printed for close on a hundred years, and, with a single exception, no English printer has reproduced in our generation one of the noble translations into Latin which occupied most of the life of Ianaeus. To a graduate not of Oxford but of Edinburgh we owe the only attempt yet made to show the mettle of the old dictator. Dr. A. J. Brock was contributing to a series of translations meant for the general reader, so that he naturally chose a text which was not of wholly professional interest. *De Temperamentis*, *De Febrium Differentiis*, and *De Sanitate tuenda* are, to the medical reader, more interesting than Galen's treatise on the *Natural Faculties*, but they would not interest at all a non-medical reader, while any intelligent man can find much in the treatise selected by Dr. Brock upon which it is profitable to meditate.

Fuchs said that Galen's immortality was due to his realization that the physician is the servant of nature. Dr. Brock has expanded this formula, which is too general to be helpful, and finds in Galen these six characteristics: (1) the high ideal which he set before the profession; (2) his insistence on immediate contact with nature as the primary condition for understanding disease; (3) his broad outlook; (4) his appreciation of the unity of the organism and the correlation of its parts; (5) his realization of the inappropriateness and inadequacy of physical formulae as explanations of physiological activities; (6) his sense of the dangers which would beset the art of medicine were it to be the prey of mere competing specialists—his belief that the whole was more than the mere sum of its parts.

If, as we may reasonably hope, the precepts and examples of such scholars as Dr. Brock lead to a revival of critical interest in the writings of Galen, we think that the state of his reputation in the twentieth century might have given him, could he have foreseen the future,

more satisfaction than his dictatorship in the fifteenth century. Galen, like the rest of us, was a complex character. He had plenty of common vanity, much combativeness, very little tolerance of others' opinions; Dr. Brock's remark, that "Galen uses what we should call distinctly immoderate language towards those who ventured to differ from the views of his master," is certainly not an over-statement. Yet, when the worst is said, the truth—or what we take to be the truth—remains that Galen was the greatest physician whose name has come down to us; he was a far greater man than Sydenham and not inferior to Harvey. He was greater than Sydenham because his outlook was broader and his courage higher. One smiles nowadays at the rashness of a Spencer or even of a Buckle in essaying to cultivate a field too wide for a single labourer. They were narrow specialists in comparison with Galen. Nor was Galen a mere scholar and compiler; his positive contributions both to anatomy and physiology would have made the spiritual fortune of a smaller man. In all his writings, for instance in the *Natural Faculties* (see p. 59 et seq. of Dr. Brock's edition), one finds passages which show the difference between the mere compiler and the experimental philosopher.

But we are afraid that the modern world will never understand how great Galen really was, because his literary powers were not of the first order. In one sense Dr. Brock is certainly right in saying that "Galen is a master of language." In another, and much more important, sense he is, we think, altogether wrong. The great masters of literature have had the gift of selection, the instinct to recognize what special matter, valuable in itself perhaps, should be left out so that the general impression desired to be conveyed is not weakened. Galen had not this gift, and until someone endowed with a rare and precious quality interprets Galen to the modern world, Galen will continue to be no more than a shadow of a name. There is no necessary connexion between such a power of writing and classical scholarship, so that the issue of further translations of Galen's work, of the same standard as Dr. Brock's, is a preliminary condition of understanding. When this condition has been fulfilled Galen's interpreter may appear. Until that time Dr. Brock's volume will hold the field, and anyone who has read it will at least forbear to speak contemptuously of those who styled Galen their master.

### AN INSTITUTE OF ANIMAL PATHOLOGY.

THE Council of the Senate of Cambridge University has presented this week its report on the offer of the Ministry of Agriculture to establish in Cambridge, in connexion with the Schools of Agriculture and Medicine, a research institute for the study of the pathology of animal diseases. The Ministry, with the concurrence of the Development Commissioners and the Treasury, offers to provide, in the first instance, a capital sum of £30,000 for investment by the University, subject to certain conditions for the establishment of a professorship of animal pathology. The Development Commissioners are not in a position to recommend any assistance towards expenditure on the study of animal diseases from funds other than the Corn Production Acts Repeal Act Fund, which is expected to be exhausted in or about 1927. But the Treasury would afterwards be prepared to consider the provision from the Exchequer of funds for carrying on schemes initiated from the Corn Acts Repeal moneys. The Minister of Agriculture, having no doubt that his successors would share his view of the paramount importance of the institute and its work, expresses the hope that the risk which the university is asked to take will not appear unreasonable. Having considered the whole matter,

<sup>1</sup> Galen on the *Natural Faculties*. With an English translation by Arthur John Brock, M.D. [Loeb Classical Library]. London: Heinemann, 1916. (10s. net.)

the Council of the Senate records its opinion that the pathology of animal diseases is a suitable subject for scientific study, and that its inclusion is desirable in the University of Cambridge, which already possesses strong schools of medicine and agriculture. It accordingly recommends that the offer of the Ministry of Agriculture and Fisheries be accepted, subject to a proviso that the University shall have no obligation to continue the institute after March, 1927, unless satisfactory financial provision for its maintenance be forthcoming from the Government or from other sources. We need scarcely add that the foundation of a chair of animal pathology at Cambridge, with an institute for research in animal diseases, has the warm support of the Regius Professor of Physics, Sir Clifford Allbutt, and of the Drapers Professor of Agriculture, Mr. T. B. Wood. The former, we may suppose, will regard it as a step towards the establishment of an institute of comparative pathology which he has advocated for many years past. The field awaiting such an institute is very wide, and its value to medicine, veterinary medicine, agriculture, and horticulture, would be incalculable. Meanwhile much good must come from the foundation of an institute of animal pathology in close liaison with the school of medicine.

#### INDIAN SERVICES.

THE Government of India has decided, in reply to a resolution in the Council of State, to appoint a Royal Commission on the Services in India. The terms of reference have not been settled, but the Government states that they will be wide in their scope. "The Commission will be required, having general regard to the necessity of maintaining a standard of administration in conformity with the responsibilities of the Crown for the government of India, and to the declared policy of Parliament in respect of increasing the association of Indians in every branch of the administration, and having particular regard to the experience now gained of the operation of the system of government established by the Government of India Act, to inquire into the organization and general conditions of service, financial and otherwise, of the superior Civil Services in India, and the best methods of ensuring and maintaining satisfactory recruitment of such numbers of Indians and Europeans respectively as may now be decided to be necessary in the light of the considerations above referred to." The step now taken has been in contemplation for some little time. The present Secretary of State for India was known to be in favour of it, and his predecessor recently pointed out the urgent need for a comprehensive inquiry. The proposal does not seem to have had a favourable reception in India, and the Indian Assembly has passed an adverse resolution, in spite of a strong speech by Sir Malcolm Hailey, who said that Indians now desired an Indian scale of pay, holding that an Indian, in his own country, should not draw the same pay as a European from England. Some provinces had already demanded that men of the province should be appointed for work in the province at provincial rates. He went on to point out that recruits were unobtainable in England, and that Parliament had the duty to see that services required to carry on the administration should have men of the same independence and character, and the same sense of duty as they had had in the past. The only body that could authoritatively settle this big question was a Royal Commission, which would have to determine the numerical proportions of Europeans and Indians. One of the services affected by existing conditions is the Indian Medical Service, and it is to be assumed that the personnel of the Royal Commission will include a member of scientific distinction acquainted with the needs of medicine and biology. The Indian Medical Service is one of the key services—some have said the key service—of British administration in India. During the war vacancies were filled by direct appointment, and this policy is being pursued. The Secretary of State has recently announced his desire to appoint immediately

thirty European officers on special terms. This announcement has raised opposition in the Indian Assembly, and the future is far from clear. The career open to European officers in the Indian Medical Service is already restricted and the development of the idea of provincializing the superior services must have the effect of still further curtailing the opportunities of European medical officers. Among the inducements offered by the Secretary of State in advertisements with regard to special recruitment in 1922-23 is that increased opportunities are now afforded for research; reference is made to the special School of Tropical Medicine in Calcutta which has been brought into existence mainly by the exertions of officers of the Indian Medical Service, and particularly those of Sir Leonard Rogers, and it is also said that the "founding of a Research Institute in Delhi is in progress." A sum had been put aside to build such an institute, but one of the recommendations of the Inchcape Commission is that the grant for research shall be cut down. We understand that in consequence the building of the institute has been postponed indefinitely, and that it is even doubtful whether it will ever be erected.

#### THE OLD AND NEW PHRENOLOGY.

THE Henderson Trust of the University of Edinburgh was founded by William Ramsay Henderson, who believed that in phrenology there was an unexplored and interesting field for scientific research. He died in 1832, and his trustees have endowed research in the structure and functions of the nervous system, and have encouraged the excellent work on the anthropometric survey of Scotland. A lecture under the auspices of the Trust was given at the University of Edinburgh on January 26th by Dr. G. Elliot Smith, F.R.S., Professor of Anatomy at University College, London. He began by praising the action of the Henderson Trust, and expressed the opinion that the investigations it was promoting were bound to lead to valuable results such as the founder of the Trust clearly contemplated when he made his bequest. The subject of Professor Elliot Smith's lecture was the old phrenology and the new; he observed that though Dr. F. J. Gall did not use the term "phrenology," he was responsible for inaugurating the remarkable doctrine to which the word was applied by his collaborator, Spurzheim, a century ago. In the light of recently acquired knowledge we were in a position to appreciate the far-reaching influence of Gall's work upon the interpretation of the anatomy and physiology of the brain, and to judge of its worth in a more dispassionate manner than was possible in the nineteenth century, when the mere mention of phrenology was enough to raise violent gusts of controversy. If Gall's actual writings—and not merely what other people attributed to him—were studied, and due attention paid to the befogged state of knowledge and opinion regarding the nervous system when his work was done, it had to be admitted that posterity had failed to give any adequate general recognition to the importance of his positive contributions to the knowledge of brain anatomy, and to the great influence his work effected in clearing away much that was nebulous, and even fatuous, in physiological theory and psychological speculation. He inaugurated the new era of cerebral localization and identified the area of the left side of the cerebrum, injury to which caused a loss of speech or inability to name things. If he was led into error in working out the details of his applications of the principles of localization, the psychological doctrines which then prevailed were to blame rather than Gall himself. The lecturer then proceeded to examine the factors that determined the variations in the relative development of the different parts of the brain, and the dominant influence of the brain in determining the size and shape of the skull. He showed from skulls that the development of the brain from the lowest stages to that of modern man was chiefly in the frontal region. An examination of the skulls of famous musicians had shown that there was a distinct area of abnormal development above the ear and that the frontal development was sometimes below the average. In ancient Egypt the religious

revolution of Akhenaton was connected with the peculiar physical type of that famous Pharaoh. Egypt lost her empire, and when she recovered her strength in the nineteenth dynasty the great Pharaohs were found to have very strong faces and well developed skulls. To illustrate this point the lecturer showed a picture of Seti the Great, to whose tomb the Tutankhamen relics, recently unearthed, are being carried. Studies he had made when in Egypt afforded evidence that the weakness of the twentieth dynasty was accompanied by peculiarities in the skulls of the late Rameses Pharaohs.

#### THE VIRUS OF INFLUENZA.

A RECENT outbreak of influenza in South Africa afforded to Sir Spencer Lister, the well known bacteriologist, an opportunity of making some important observations which he describes in the *South African Medical Record* of November, 1922. He recalls that when influenza made its appearance in Johannesburg during the pandemic of 1918, Pfeiffer's bacillus—relatively absent in that community before the outbreak—was found by him in no fewer than 53 out of 56 cases dying with pulmonary complications; but his attempts to detect a filter-passing virus either by experiment or by culture failed. It is the more interesting, therefore, to learn that in this recent outbreak he has succeeded in satisfying himself of the presence of an anaerobic filter-passing organism similar to that defined by the careful studies of Olitsky and Gates in New York, and confirmed by Gordon in the London outbreak during the early months of 1922, as reported in our columns on August 19th, 1922. By sowing in Noguchi medium the filtered nasopharyngeal washings taken within thirty-six hours of the onset of influenza Lister succeeded in obtaining a culture of the filter passer in 5 out of 15 cases. His comments on the case with which the presence of this very minute organism may be overlooked without unusual concentration of gaze and accurate focusing. The stain which he found most successful for demonstrating the presence of the organism in films was Loeffler's alkaline methylene blue, the latter a specimen of Grubler's pre-war stock. The size of the organism was 0.15 of a micron, which is smaller than the organism found by Gordon, who estimated it to be 0.2 of a micron in diameter—a difference probably to be ascribed to the different methods of staining, as the latter observer employed prolonged staining in Giemsa's solution; he has seen preparations of Lister's organism, and agrees that it is identical with that observed by him in films of the nasal secretion and in cultures from the London cases. Lister has taken matters a stage farther than previous investigators by carrying out a preliminary experiment on human volunteers with cultures of this filter-passing organism. Sixty c.cm. of a culture in the second generation were divided into three portions—one-third was placed in a spraying bottle, one-third passed through a Berkefeld V filter and the filtrate placed in a second bottle, and the remaining third treated for half an hour to 56° C. and placed in a third spraying bottle. Six individuals were then sprayed with the unaltered culture, seven received the filtrate, and six the heated culture, about 1.5 c.cm. being sprayed into the nose and throat of each volunteer. The only one of these nineteen volunteers who complained of any discomfort had received the unaltered culture, and developed a typical attack of uncomplicated influenza beginning nineteen hours after spraying. The minute bodies were observed in smears of his nasal secretion, and a nasal washing was filtered through a Berkefeld candle. This filtrate on cultivation in Noguchi medium gave in five days a profuse growth of the organism. Two other individuals also in this first group that received the unaltered culture had a slight rise of temperature, and one of them showed a well marked leucopenia. Although, as Sir Spencer Lister is careful to point out, this result is not sufficiently conclusive to establish the filter passer as the cause of influenza, it is distinctly encouraging, and further reports of his enterprising investigations will be awaited with interest.

#### INSULIN.

THE many problems of physiological and therapeutic interest raised by recent investigation in Toronto of the internal secretion of the pancreas are beginning to attract attention in France. Dr. Gustave Monod, who has often acted as intermediary between the British and French professions, brought the subject before the Paris Therapeutical Society recently, and at the meeting of the Académie de Médecine on January 16th a short discussion followed a paper by M. Léon Blum of Strasbourg on the treatment of diabetes mellitus by insulin. Dr. Blum prepared insulin in accordance with the methods described in our columns by Macleod, Banting and his colleagues, and used it in two cases. Both patients were put on strict diet for a period, but continued to pass a considerable quantity of sugar in the urine; in both cases injection of the insulin M. Blum had prepared was followed by disappearance of the sugar. When the injections were discontinued the sugar and the accompanying symptoms returned. As for the practical value of the treatment, Dr. Blum arrives at a conclusion almost identical with one of those reached by Banting and his colleagues—namely, that in the present stage resort should be had to insulin in cases of diabetes in which it is essential to produce a rapid effect—such cases, for instance, as those of threatened gangrene or when a surgical operation is contemplated. In commenting on Dr. Blum's paper, Professor Achard related certain experiments he had undertaken at various times, and in particular some recent investigations by his pupil Gardin, hitherto unpublished. He prepared an aqueous decoction of pig's pancreas in a slightly acid medium, which was neutralized before injection into a vein. In all the cases treated the amount of sugar diminished and the respiratory quotient increased. In two other cases evidence was obtained that the extract given by the mouth at the same time as a dose of sugar increased the respiratory quotient, thus proving that it caused immediate combustion of sugar. Professor Achard expressed the opinion that the administration of the hormone of the pancreas would probably be a very useful method of treating diabetes, especially cases attended by severe acidosis. Professor Gley, after reviewing the situation and relating some early experiments of his own, concluded by saying that the great merit of his own, and his fellow workers was that they had succeeded in obtaining active extracts direct from the animal pancreas and had carefully studied the physiological effects of these extracts.

#### PHYSIOLOGICAL EFFECT OF HIGH ALTITUDES.

MR. J. BARCROFT, F.R.S., communicated to the Royal Society on January 18th a paper discussing the observations made in the Andes on the effect of high altitude on the physiological processes of the human body. He began by enumerating the three principal factors which appear to have a positive influence in acclimatization. The first is the increase in total ventilation, which usually raises the alveolar oxygen pressure ten or twelve millimetres higher than it would otherwise be; the second is the rise in the oxygen dissociation curve so that at any oxygen pressure the haemoglobin will take up more oxygen than before; and the third is the rise in the number of red corpuscles, and correspondingly in the quantity of haemoglobin. These factors, though they were provisionally treated as independent variables, are not so in reality, for blood can be made artificially to resemble high-altitude blood by shaking out the CO<sub>2</sub> and then withdrawing a portion of the plasma, so that the blood is richer in corpuscles. Such blood has been found to give, at the alveolar CO<sub>2</sub> pressure of the Andes, a reaction which is apparently almost unchanged, or even more acid, as measured by the ratio of combined to free CO<sub>2</sub>; a more alkaline reaction by the platinum electrode; and an oxygen dissociation curve which rises apparently out of proportion to the change in reaction. Herein, Mr. Barcroft believes, is the essence of the acclimatory process. The possibility of the oxygen dissociation curve altering owing to a specific loss of CO<sub>2</sub> could be ruled out. There was an

increase in the haemoglobin value of the blood and in the red cell count in all cases. On making the ascent there was a marked increase in the number of reticulated red cells; after the descent these cells fell to below their normal percentage. In the natives the ratio of reticulated to unreticulated red cells was not greatly increased, but the absolute number of reticulated cells per cubic millimetre was about 50 per cent. greater than normal. This was held to point to a hypertrophy in the bone marrow. There were no nucleated red cells. The increase in red blood corpuscles was such as to cause an absolute increase in the amount of oxygen in each cubic centimetre of blood in the majority of cases, in spite of the decrease in saturation. A number of mental tests of the ordinary type were performed at Cerro and at sea-level. These revealed no particular mental disability in the Andes, but, in the opinion of the observers themselves, as well as in that of psychologists who had been consulted, had shown rather that these tests were inadequate than that the mental efficiency was unimpaired. A number of tests were made to discover whether the pressure of oxygen in the blood was or was not higher than that in the alveolar air. In all cases they were so nearly the same that the passage of gas through the pulmonary epithelium was attributed to diffusion.

#### ZINC POISONING.

A sudden outbreak of illness which occurred recently amongst the inmates of a large institution near London indicates that danger may arise from the use of galvanized iron vessels for cooking purposes. About 400 persons were served at tea with hot stewed apples. The remainder of the meal consisted of bread and margarine and tea. Within a few minutes more than 200 of whose who partook of the stew complained of dizziness, sickness or a feeling of sickness, colic, and tightness in the throat. There was some diarrhoea, but no double vision. The medical officer at once administered doses of bismuth and chalk mixture, and within a short time most of the sufferers had recovered and were able to take supper at 7.45 p.m. Only ten persons were at all seriously ill, and all of them were able to carry out their ordinary work next day, so that obviously the effects of the poisoning soon passed off. The apples were freshly gathered and were stewed in large galvanized iron "skeps," which were placed in iron steamers. The skeps were used because it had been found on a previous occasion that the apples became black if placed directly in the steamers. A chemical examination of some of the stewed apples remaining over from the meal showed that they contained 7 grains of zinc, expressed as zinc oxide, in the pound; this is equivalent to 25 grains of hydrated zinc sulphate to the pound. Taken internally zinc sulphate is very slowly absorbed, and any effect it produces is probably due to its local action on the alimentary canal. The dose mentioned in the *Pharmacopoeia* is 1 to 3 grains. Its emetic effect is probably to be attributed to its irritating action on the stomach. The emetic dose given in the *Pharmacopoeia* is 10 to 30 grains. Each person consuming the stew may be assumed to have taken 18 to 20 grains of zinc sulphate. As it is well known that vegetable acid can act on metals the cause of the outbreak hardly seemed in doubt from the first. Galvanized iron vessels are seldom or never used for domestic cooking, but the incident here related shows that managers of institutions should recognize the risk and prohibit the use of galvanized iron vessels for containing food materials, which are commonly acid, and therefore capable of dissolving zinc.

#### DENTAL PRACTICE IN EGYPT.

THE Dentists Act of 1921, prohibiting the practice of dentistry by unregistered persons and establishing a Dental Board and a new and much expanded *Dentists Register* for this country, has had its counterpart in Egypt. The last annual report of the Egyptian Department of Public Health mentions the introduction of a new law giving greater powers for dealing

with unqualified dental practice, which was gradually becoming a serious public danger. The penalties under the old law, it is said, afforded an insufficient deterrent to a gradually increasing horde of ignorant charlatans who found in the practice of dentistry a lucrative source of gain. Just as in this country, the new Egyptian law makes a distinction in favour of those unqualified practitioners who through long practice had acquired a certain empirical knowledge of the art. It was felt that "to remove suddenly what had previously been an accepted means of livelihood would have entailed a considerable hardship upon many individuals whose claims to dental knowledge were sufficiently justified to remove them from the category of those who constituted an actual danger to the public." Certain transitory clauses were therefore included providing for the grant of a modified form of permit to such as could prove that they had been actually in continuous practice as dentists for at least ten years before the promulgation of the law, and who could sufficiently justify their claims to be allowed to practise their art by passing a special examination held by a board of examiners constituted for the purpose. This rigorous condition—much more exacting than the corresponding conditions laid down in Clause 3 of the British Dentists Act—is no doubt explained by the differences between unqualified dentistry as practised in Egypt and in this country. We learn that considerable difficulty was experienced in deciding upon the claims submitted with regard to length of practice. The nature of the difficulty may be guessed from the following discreet sentence: "In many cases the Committee formed to inquire into these [claims] was placed in the position of having to view with considerable suspicion some of the documentary evidence submitted." In the outcome 218 candidates were admitted to the technical examination, of whom 25 were rejected because they could not satisfy the examiners that they possessed sufficient practical knowledge to justify permission to continue their calling. To guard the primitive-minded people of Egypt from being practised upon by incompetent persons must be no easy task in these days of political uncertainty.

#### ERYTHREDEMA OR THE "PINK DISEASE."

THE abstract of Zahorsky's paper on the "pink disease" in the issue of January 20th (p. 123) has aroused considerable interest, and has called attention to a paper by Dr. W. E. Hume of Newcastle published in this JOURNAL on September 2nd, 1911. This author collected and described a series of cases of general oedema in children following gastro-enteritis. In the thirteen cases classified by him, in nine diarrhoea and vomiting is recorded; oedema, universal or limited to the hands or feet, was present in every case, and cyanosis of the extremities, slight or marked, in ten cases. The ages of the patients varied from 13 months to 4 years. These cases differ from those described by Zahorsky in the absence of the striking and usually early erythematous eruptions and of the severe pruritus, and in the presence of the initial diarrhoea and vomiting which are almost constant features in Hume's series. The swollen and cyanotic condition of the hands and feet was apparently similar in both series.

#### POST-GRADUATE EDUCATION IN LONDON.

THE Fellowship of Medicine has invited representatives from the staffs of the hospitals interested in the establishment of a scheme of post-graduate education in London to a conference, to be held, by kind permission of the Royal Society of Medicine, at 1, Wimpole Street, on Thursday, February 8th, at 5 p.m. The object with which the conference has been arranged is to afford an opportunity of discussing how far the Fellowship of Medicine can continue to promote the cause of post-graduate instruction and hasten the time when a permanent and comprehensive organization in London is an accomplished fact. Larger schemes, in which the University of London and the University Grants Committee are interested, are, we believe, under consideration, but in the most fortunate circumstances it must be some considerable time

before they can come into effect. The Fellowship of Medicine was founded to help medical visitors to London, more particularly on the social side. London is not inhospitable, but its hospitality is patchy. The Fellowship owed much to the initiation of Sir William Osler, who had also taken the lead in founding the Post-Graduate Medical Association. The two bodies have been amalgamated and have kept the flag flying since the beginning of 1919. The combined body deserves, perhaps, more credit for this than it has received; it may, we hope, be enabled to continue its work of co-ordination and propaganda.

#### THE CIVIL PROFESSION AND THE MEDICAL SERVICES.

A discussion on co-operation between the medical services of the civil and armed forces in peace and during war will take place at the meeting of the War Section of the Royal Society of Medicine on Monday, February 12th, at 5 p.m. The subject will be introduced by Surgeon Commander R. J. McKeown, O.B.E., M.B., R.N., and Surgeon Commander A. Gaskell, C.B., R.N. The discussion will be opened by Air Commodore D. Munro, C.S.I., F.R.C.S., D.M.S., R.A.F., and continued by Major-General C. E. Pollock, C.B., C.B.E., D.S.O., D.D.G., A.M.S., Sir Crisp English, K.C.M.G., F.R.C.S., and others. The subject, it is believed, will be of interest to all medical men, and visitors, whether members of the Section or not, will be welcomed.

We have to announce with deep regret the death, on January 28th, after a long illness, of Dr. James Ritchie, professor of bacteriology in the University of Edinburgh. We hope to publish an account of his career in an early issue.

### NoVA et VETERA.

#### DR. THOMAS SHORT: AN EARLY MEDICAL STATISTICIAN.

"Dr. THOMAS SHORT," wrote Dr. Creighton, "a man of great industry, about the middle of last century obtained access to a large number of parish registers, and worked an infinite number of arithmetical exercises upon their figures. His abstract results or conclusions are colourless and unimpressive, as statistical results are apt to be for the average concrete mind; nor can they be made to illustrate the epidemic history of Britain with the help of his companion volumes—*A General Chronological History of the Air, Weather, Seasons, Meteors, etc.*—for these extraordinary annals are for the most part loosely compiled from foreign sources, bringing into one focus the most scattered references to disease in any part of Europe, and that too without criticism of authorities but often with surprising credulity and inaccuracy. That so much statistical or arithmetical zeal and exhaustiveness (in the work of 1750) should go with so total a deficiency of the critical and historical sense (in the work of 1749) is noteworthy, and perhaps not unparalleled in modern times."

We are not in a position to rebut Dr. Creighton's charges against the *General Chronological History*, never having seen a copy of that rare book; we will, however, roundly assert that *New Observations, Natural, Moral, Civil, Political, and Medical, on City, Town, and Country Bills of Mortality*, if unimpressive are certainly not colourless. Dr. Thomas Short's arithmetical exercises led him to rather gloomy conclusions, which he stated in very vigorous terms. The birth controllers of the period are informed that

"If Whoredom be a Fault, Suicide is a far greater Crime: by Suicide is meant, not only the Destruction of real Beings in the Womb, Birth, or immediately after; but all nefarious Practices used by wicked Wretches to prevent Conception from their carnal Gratification."

Short was an adherent to the House of Hanover, and was glad to be able to point out that by their accession "Industry was promoted and Trade vastly increased, to the Accumulation of Riches."

But unfortunately there were other effects:

"For the Truth of these sad Effects, I might appeal from the Registers, to the City Table of Casualties, and see which Periods have produced most hereditary Gouts, venereal Taints, in which are most Apoplexies, or violent Deaths, either by the Executioner, or the Wretches' own butcherly Hands have been most employed, Drunkenness and Swearing most common. I might appeal further to the Death of Infants then and now, whether 30 or 47 per cent. are the greater Numbers; and whether 2 of 17 that died of the Small-pox, or 4 in 21 be the most, or one of 35 that died then of Convulsions, or 9 of 35 that die now of them."

Short's medical philosophy was iatro-mechanical rather than Galenical and—*horresco referens*—he was jocular at the expense of Sydenham. He has a chronology of epidemics and we read: "61 to 64, Sydenham's depuratory Fevers, which, however, in 65 depurated to the fatallest Plague ever the Metropolis felt." But the general opinion of his colleagues was much the same as Sydenham's, as the following remarks show:

"Some take in a larger Circle of Medicines, but from some false Idol (as Bayliri terms it) or others may prescribe in such a random, tumultuous Way, as rarely succeeds well. Others may imagine, that keeping steadily to the same Intentions in the same Diseases, at all Times, will be equally successful at all Times. . . . is more false: Others have a dextrous Smatch of the Gout, Fever, Scurvy, or Hippo in all Diseases; others will relish nothing but what is the Product of the Furnace, by Crucible and Retort; or believe nothing but what they see with their own Eyes, or hear with their own Ears, as though all were Liars but they, and thereby give suspicion that they themselves are such."

As a statistician, Short's place in order of merit, as in time, is after Graunt and before Heberden. He had neither the originality nor concentration of Graunt, but his industry was, as Creighton said, immense. He has collected data in some instances ranging over a full 200 years, from the first introduction of parish registers by order of Henry VIII's minister Cromwell. He has compared the results in parishes in different soils and at different elevations, he has correlated mortality with air temperature and barometric pressure and printed all his evidence. Of course, the chief difficulty of interpretation is the absence of a census record. Thus Short always used the ratio of christenings to marriages as the just measure of fertility; no other measure was available. But naturally it is only correct when the frequency of marriages and the population "at risk" are constant. The ratio will understate the gross fertility if marriages are increasing. It would not be safe to infer from his data that the population was more prolific in his second period (roughly the 100 years down to his time) than in the first period (the middle of the sixteenth to the middle of the seventeenth century) because the ratios of christenings to weddings were respectively 4.3 and 3.99. At the same time it is proper to notice that there is a high correlation between his ratio and more exact measures even in a rapidly increasing population.

Thus in England and Wales in the years 1871, 1881, 1891, 1901, and 1911, the ratios of births to marriages were 4.2, 4.5, 4.0, 3.6, 3.2. The legitimate births per 1,000 married women aged 15 to 45 were 288.4, 284.9, 263.8, 234.2, 196.2. Turning the two series into percentages of the first figure of each we have 100, 107, 95, 86, 76: 100, 99, 93, 81, 68.

The inference Short would have drawn from the former series would not be substantially modified by the latter. The same kind of criticism applies to reasoning from the ratio of burials to christenings and is here rather more formidable because of the consequence of migration or, as Short termed it, export. He dealt with the latter point very ingeniously, and proposed a method of computing the number of imports. His method may be shown by an example. It depends upon the assumption that 57 per cent. died before attaining the age of 20. One of his tables gives 211,233 baptisms; he deducts 57 per cent. and is left with 98,071 (so he says, but it should be 90,830, we think). But the table gives 136,942 married, but all which, he says, is 38,867 more than the survivors, per cent. the survivors to 20 do not marry; an allowance of 5 per cent. for the celibates reduces the married survivors to 129,972. Subtracting this from the numbers married he gets a balance of 43,963 for imports and unregistered births. Of course, he had no means of measuring the age distributions in the parishes, but he was fully aware that

"It is Idleness or Ignorance to estimate the Healthiness of a Place, from its having a few old People; for such Places are inhabitable, where some Constitutions (especially such as are in them) will not weather out Life to old Age in any Soil Situation."

With that sensible remark we take leave of Dr. Thomas Short, whose book contains more wit and much more wisdom than many newer treatises.

# The Jenner Celebrations.

## PARIS.

### THE CENTENARY OF JENNER AT THE ACADEMIE DE MEDECINE.

[FROM OUR PARIS CORRESPONDENT.]

THE meeting of the Académie de Médecine on January 23rd was devoted to the praise of Jenner. The famous Salle des Pas Perdus presented an unwonted aspect; it echoed to the feet of many visitors, for there was displayed in it a collection of all that could be got together in the way of documents concerning Jenner and the beginning of vaccination. The magnitude of the collection was all the more remarkable because the Jenner exhibition in London must have prevented the loan of many interesting objects. Apart from some valuable relics kindly lent to the British delegates the exhibition was entirely the work of the Continental admirers of the great man: books, portraits, medals, china, caricatures, all were to be seen; Dr. Cumston had brought from Geneva a unique example of the famous engraving by Scriven after the portrait by J. R. Smith—unique because it was in colours. The special numbers of the *BRITISH MEDICAL JOURNAL*—the Jenner Number, 1896, and the Vaccination Number, 1902—were given a prominent place. Dr. Vitoux, the well known Parisian collector, exhibited some autographs, one of them showing that the *crise des logements* even then needed a preventive vaccine:

My dear Madam,

I am at length in London but have not yet been able to get apartments, except at au hotel. When I have, you shall again hear from me.

Imperial Hotel, Covent Garden.

Edw. Jenner.

Now the meeting opens; the president, Professor CHAUFFARD, and the committee enter, wearing plumed cocked hats and regulation embroidered coats. The Minister of Hygiene represents the Government of the Republic, and Lord Crewe, the British Ambassador, is represented by the First Secretary to the Embassy. A large number of foreign guests have accepted the invitation to France, and in the foremost seats we see the delegates of Belgium, Canada, Greece, Holland, Italy, Peru, Portugal, Rumania, Sweden, Switzerland, Czechoslovakia, Tunis, and Turkey. Need I add that our English friends were represented? I need not, for the representatives are at home in Paris and belong to the academic family; Dr. R. O. Moon representing the Royal College of Physicians of London, Sir Ronald Ross, K.C.B., the Ministry of Health, and Sir St. Clair Thomson and Sir Almroth Wright the Royal Society of Medicine.

Professor CHAUFFARD gave a short and charming address, in which he traced the history of the fight against small-pox and described what manner of man Jenner was. Then Dr. CANUS, Directeur de l'Institut Supérieur de Vaccine, dealt with Jenner's work from the scientific point of view. This was the *plat de résistance* of the occasion. Then came Professor TEISSIER, who in vivid and eloquent words related the share of French science and of the Académie de Médecine in the dissemination of knowledge of the new methods. He quoted some striking figures. During the war of 1870-71—a short war, with relatively few men engaged—the French army had 200,000 cases of small-pox, and nearly 30,000 deaths from that cause. During the recent war, with an army of our million men, mobilized for four years and a half, only our cases occurred, and these four imported. Dr. JEANSELINE sketched the progress of vaccination in the French colonies, describing it as an agent of civilization; and Professor ESRIER recalled the part played by Genevese physicians in the propagation of vaccination.

Dr. SOUVENS, the annual secretary of the Académie, read a paper on small-pox in London, prepared by Dr. BLAXALL, and expressed his regret and that of the audience that the thor had been unable to read it himself.

Sir ST. CLAIR THOMSON, in the name of the Royal Society of Medicine, won the heart of the audience with a spirited Thomsonian speech delivered in the purest Parisian French. He presented to the Académie de Médecine a fine engraving of Jenner, the gift of Dr. Walter S. A. Griffith, and also the picture of the twenty-one founders of the Medical Society of London with the portrait of Jenner in the background. He pointed out how Jenner was the precursor of Pasteur, just as Pasteur opened the way to Lister.

Professor ACHARD, secretary-general of the Académie, then read the following address of gratitude and sympathy, signed by the President of the British Medical Association and the Chairman of Council, in the name of the 24,000 members of the Association.

#### TO THE ACADEMIE DE MEDECINE

On the Occasion of its Celebration of the Centenary of Edward Jenner's Death.

The British Medical Association has heard with great pleasure that the Académie de Médecine is about to celebrate the centenary of the death of a great Englishman, Edward Jenner. The Association desires to express its warm appreciation of this act of spontaneous generosity. The Association does not forget the graceful words in which a great Frenchman, Louis Pasteur, in his address to the International Medical Congress in London in 1881, referred to Jenner: "I have," he said, "given to the term 'vaccination' an extension which science I hope will accept as a just homage to the immense services rendered by one of the greatest of Englishmen—Edward Jenner." The British Medical Association has over 23,000 members who are practising medicine in all parts of the British Empire. Each one of them, wherever his lines may be cast, is, alike in his conception of the principles of medicine and in his daily application of these principles to the alleviation of suffering and the prevention of disease, under an immense debt to Pasteur. The British Medical Association is proud to know that Pasteur himself desired to associate with his own great achievements the name of Edward Jenner.

Signed on behalf of the Association,

WILLIAM MACEWEN,  
President.

R. A. BOLAM, M.D.,  
Chairman of Council.

January 19th, 1923.

Professor Achard concluded by showing a number of lantern slides illustrating the life and work of Jenner.

In the evening a banquet was held to which your correspondent was specially invited. Our visitors received a most cordial welcome, and when Sir Almroth Wright, Sir Ronald Ross, and Dr. Moon in succession rose to address the company in French each one of them was greeted by a *ban* given vigorously in the French fashion.

That the centenary of the death of Jenner and of the birth of Pasteur should have fallen almost at the same time seems providential; these two benefactors of mankind succeeded each other in time as they did in genius. It is impossible to put into dry words the atmosphere which pervaded the day. The symbolic significance of the presence of representatives of so many countries coming together in France to render homage to a great Englishman appealed alike to eye and heart. We live in difficult times, but if we know how to lift ourselves high enough we shall breathe a purer air. Jenner, Pasteur—these names arouse in us the highest kind of enthusiasm; they shine upon the peoples like the sun, which has no regard for frontiers. The relations of our two great masters, like the relations of our two races—I borrow here from Sir St. Clair Thomson's peroration—may they not be expressed in these two lines from Shakespeare:

"Are we not made as notes of music are,  
For one another, though dissimilar?"

## LONDON.

## COMMEMORATION AT THE ROYAL SOCIETY OF MEDICINE.

The centenary of the death of Edward Jenner was celebrated at a special meeting of the Royal Society of Medicine on January 26th, when the President of the Society, Sir WILLIAM HALE-WHITE, delivered an address. The members of the audience, on arrival outside the building, were diligently plied with antivaccinationist leaflets—in the circumstances a grotesque misdirection of energy.

On the platform William Hobday's portrait of Jenner, which has been presented to the Society by Dr. W. S. A. Griffith, was displayed. The portrait, painted in 1821, represents Jenner seated, dressed in a cloak, with a fur collar, one arm resting on a volume lettered "John Hunter," while a paper relating to vaccination lies on the table.

## JENNER: NATURALIST, PATHOLOGIST, AND COUNTRY DOCTOR.

ADDRESS BY SIR W. HALE-WHITE.

Sir WILLIAM HALE-WHITE devoted his address to a delineation of Jenner's personality, and not an appraisalment of his great discovery, which he judged to be unnecessary before such an audience. He remarked that it was fitting to commemorate the centenary in the Royal Society of Medicine, because Jenner was one of the foundation members of the former Medical and Chirurgical Society, and contributed two papers to the first volume of its *Transactions*.\*

Jenner was born at Berkeley, in Gloucestershire, in 1749. He was the son of Stephen Jenner, vicar of the parish, who had been tutor to one of the Earls of Berkeley. His father died soon after Edward's birth, and the boy was brought up by his brother, also a Rev. Stephen Jenner. At 8 years of age he went to school at Wotton-under-Edge, and later to a tutor at Cirencester. After a pupilage to Mr. Ludlow, a practitioner at Sodbury, in Gloucestershire, Jenner came to London at the age of 21, and for two years resided in the house of John Hunter. "Nothing could have been more fortunate, for both men were enthusiastic naturalists, always observing, inquiring, and speculating." On Hunter's recommendation Jenner was appointed to examine and prepare the specimens of natural history brought back by Captain Cook in 1771; he declined the offer of the post of naturalist to the expedition which sailed in the following year.

*The Soul of a Naturalist.*

After Jenner's return to Gloucestershire many letters passed between the two until Hunter's death in 1793. All Jenner's letters had been destroyed, but from Hunter's it was evident that Jenner made many observations for Hunter on the hibernation of animals. In one letter Hunter thus disposed of Jenner's disappointment in love:

"I own I was glad when I heard you was [to be] married to a woman of fortune; but let her go, never mind her. I shall employ you with hedgehogs, for I do not know how far I may trust mine. I want you to get a hedgehog at the beginning of winter and weigh him; put him in your garden, and let him have some leaves, hay, or straw to cover himself with, which he will do; then weigh him in the spring, and see what he has lost. Secondly, I want you to kill one at the beginning of the winter to see how fat he is, and another in the spring to see what he has lost of his fat. Thirdly, when the weather is very cold, and about the month of January, I wish you would make a hole in one of their bellies, and put the thermometer down into the pelvis, and see the height of the mercury."

Probably no other disappointed lover had been bidden to seek solace in hedgehogs! Many other letters of Hunter were concerned with these animals, and, indeed, nine-tenths of the letters were taken up with requests for specimens or for experiments in natural history. That Jenner had in him the soul of a naturalist was shown by the fact that one of Hunter's letters began: "I do not know anyone I would sooner write to than you; I do not know anybody I am so much obliged to." It was Hunter who stimulated Jenner to study the habits of the cuckoo, on which subject Jenner sent a communication to the Royal Society in 1788.

*The Complete Country Practitioner.*

When Jenner took up general practice in Berkeley (in 1773) his talents gained him confidence and esteem, and his practice

and reputation rapidly increased. A patient in the Gloucester infirmary requiring an immediate operation, and neither of the surgeons being available, Jenner, sixteen miles away, was summoned, and performed the operation successfully. He was disappointed by the uncertainty of the action of tartar emetic, and published an improved process, which led Hunter to write: "I am puffing off your tartar as the tartar of all tartars. . . . Let it be called Jenner's tartar emetic." In 1777 Hunter wrote to Jenner, saying that he was ill, and Jenner, suspecting that he was suffering from angina pectoris, visited him and found the surmise correct. He wrote to Heberden to say that, as a result of *post-mortem* examinations, he had come to the conclusion that angina pectoris was due to disease of the coronary arteries, but that he hesitated to make his opinion public or to tell Hunter for fear of distressing his friend. This was the first account of the association of diseased coronary arteries and angina pectoris. In a letter to Dr. Parry of Bath Jenner gave a quaint account of his first case:

"I was making a transverse section of the heart pretty near its base, when my knife struck against something so hard and gritty as to notch it. I well remember looking up at the ceiling, which was old and crumbling, conceiving that some plaster had fallen down. But on a further scrutiny the real cause appeared: the coronaries were become bony canals."

He read a paper on this subject before a society of doctors, called the "Medico-Convivial," which met at a country inn at Rodborough. Another paper of his was on heart disease occurring during rheumatism. Jenner was popular with his fellow doctors and with his patients. He frequently spent days in the houses of particular friends, especially if any of them were ill, carrying on his practice from his temporary quarters. Educated people loved his conversation, and he used to encourage those whom he liked to ride with him on his rounds. When he left a patient's house often some of the family would ask permission to ride home with him even if it was midnight. His range of conversation was vast; he was often witty, was fond of epigram, and was no mean poet; also he could sing and play the violin and flute.

In 1788 Jenner married Miss Catherine Kingscote, and in the following year his son Edward was born, John Hunter standing as godfather. In 1792 the fatigues of an ever-increasing practice had become so great that Jenner resolved to practise solely as a physician, and accordingly he obtained the M.D. degree of St. Andrews. His friend Gardner thus described his appearance at this time:

"His height was rather under the middle size, his person was robust but active and well formed. In dress he was particularly neat. . . . He was dressed in a blue coat and yellow buttons, buckskins, and well polished jockey boots with handsome silver spurs, and he carried a smart whip with a silver handle. His hair, after the fashion of the times, was done up in a club, and he wore a broad-brimmed hat."

"Everything we know of him," said Sir William Hale-White, "indicates that he was usually cheerful and sociable, very occasionally he was depressed, and we find him complaining that he was an example of the sin of indolence. Many busy people, being aware how much there is to do in the world, at times blame themselves for this."

*The Great Discovery.*

When as a youth Jenner was an apprentice at Sodbury, a young woman came to his master's house, and on small-pox being mentioned said at once, "I cannot take that disease, for I have had cow-pox." That remark set Jenner thinking, and afterwards he talked about it to Hunter, who characteristically told him, "Don't think, but try, be patient, be accurate." When he went into practice he discussed the question with other doctors, who were sceptical, for they said that cow-pox often did not protect from small-pox. This difficulty Jenner overcame by finding that the eruptions on the udders of cows were not always true cow-pox, and that the vesicles of cow-pox were not equally virulent at all periods of their development. By 1780 he believed he was in sight of a means of completely eradicating small-pox by inoculation with cow-pox. In 1789 he inoculated his eldest son with swine-pox matter; subsequently variolous matter was inserted, and again in two subsequent years. None of these three small-pox inoculations caused small-pox in the child. In 1796 matter was taken from the hand of Sarah Nelmes,

\* "Distemper in dogs" and "Two cases of small-pox infection communicated to the foetus in utero, under peculiar circumstances," both contributed in 1805.

who had been infected with cow-pox by her master's cows, and inserted into the arm of James Phipps, aged 8 years. Two months later variolous matter was taken immediately from a small-pox pustule and carefully inserted by several incisions. Days of the intensest anxiety to Jenner dragged by, but James Phipps did not have small-pox. Jenner wrote to his friend Gardner on July 19th, 1798:

"As I promised to let you know how I proceeded in my inquiry into the nature of that singular disease the cow-pox, and being fully satisfied how much you feel interested in its success, you will be gratified in hearing that I have at length accomplished what I have been so long waiting for, the passing of the vaccine virus from one human being to another by the ordinary mode of inoculation.

"A boy named Phipps was inoculated in the arm from a pustule on the hand of a young woman who was infected by her master's cows. Having never seen the disease but in its casual way before—that is, when communicated from the cow to the hand of the milker—I was astonished at the close resemblance of the pustules, in some of their stages, to the variolous pustules. But now listen to the most delightful part of my story. The boy has since been inoculated for the small-pox, which, as I ventured to predict, produced no effect. I shall now pursue my experiments with redoubled ardour."

In 1798 Jenner published his famous little book, called for short the *Inquiry*. It contained the record of numerous cases. Some of them showed that persons who had had cow-pox did not get small-pox either when exposed to it or when inoculated with it; some showed that if a person had had small-pox he was protected against cow-pox; some that those inoculated with cow-pox were immune to small-pox inoculations, and others again that material taken from the cow-pox pustule in the human being might be used to inoculate other human beings, who were thus equally protected from small-pox.

#### World-wide Progress of Vaccination.

After the publication of his book Jenner's correspondence left him little time for practice. Most of his contemporaries in the profession saw that a great discovery had been made, though there were a few who gave trouble, for Jenner wrote: "Brickbats and hostile weapons of every sort are flying thick around me"; and, "I am beset on all sides by snarling fellows." The *Inquiry* found its way to the Continent in 1799. The day on which the boy Phipps had been vaccinated—May 14th—became an annual festival in Berlin. The French Government offered vaccination gratuitously to all who could not pay for it. Thanks to Lettsom, vaccination made its way to America. Jenner himself offered a thousand guineas towards the cost of getting vaccination to India, but he was not called upon for this money, because De Carro of Vienna had already been the means of introducing it there. By decree of the Dowager Empress of Russia, the first child in Russia to be vaccinated was named Vaccinoff, and provision was settled on her for life.

Meanwhile, such was Jenner's occupation with journeys, correspondence, and his own practice, that his practice disappeared. He ought to be rewarded by Parliament. A petition accordingly was presented, and was referred to a committee, which advised a grant. The sum of £10,000 was voted in the House of Commons. Other honours were heaped upon him, but what he appreciated most was the praise of members of his own profession. Sir W. Hale-White gave an account of Jenner's appearances during a long debate, occupying several successive nights, in the Physical Society of Guy's Hospital. On entering the theatre he was constantly received with universal and rapturous applause. A pamphlet by John Birch, surgeon to St. Thomas's Hospital, and an opponent of vaccination, was interesting in this connexion:

"The anniversary of Mr. Guy's Hospital was held in 1802, where I expected to meet the professors, the medical gentlemen, and the students on the same terms as usual. What was my surprise to find that the sole business of the meeting was to begin a canvass for names to a Petition to Parliament in support of Dr. Jenner's bill. I refused to sign it. My surprise was increased after dinner to find that toasts and songs and compliments from one professor to another in honour of vaccination were the order of the day."

Jenner's friends thought that he would make a handsome income if he settled in London, and consequently he started practice at Hertford Street, Mayfair, but it was a failure. Most persons seemed to consider that as he had a grant he was the servant of the public (although the grant was not paid for two years, and when it was paid £1,000 was deducted for expenses). After a fair trial, he relinquished the London practice and returned to Berkeley, becoming again the village doctor. The London experiment had been costly, and his supporters brought before Parliament the question of a further

grant. The Royal College of Physicians, on the instruction of the Government, reported on the subject of vaccination in 1807, under the signature of Sir Lucas Pepys, the President, and stated that the truth of the practice "seems to be established as firmly as the nature of such a question admits." As a result of this report the Chancellor of the Exchequer proposed a grant of £10,000, which, by amendment in the House, was raised to £20,000, with the fortunate condition for Jenner that it was to be free of fees.

#### Jenner's Last Twenty Years.

Jenner now lived at his house, "The Chantry," in Berkeley, doing the work of an ordinary country practitioner. In the garden was an arbour in which he used to vaccinate the poor gratuitously. Sometimes he visited Cheltenham and Bath, occasionally he had the opportunity of seeing celebrated visitors to his neighbourhood. He was as eager as ever in the study of nature; a charming note of his described how moths fed upon the night-blowing primrose. He also did much work on the migration of birds. "In no wise was he puffed up with his fame. He remained a simple, unostentatious man, a friend of his neighbours, whom he liked to meet at dinner. He freely gave of that most valuable of all commodities, his time; he was assiduous as a magistrate, he would listen to all callers, rich and poor, at whatever time they came to him. He was particularly cordial to all his fellow practitioners, and especially liked talking with the younger of them. His kindness to the poor was continual. Phipps (the subject of his vaccination experiment) became very ill; therefore, as he lived in a miserable place, Jenner built him a comfortable cottage, himself stocking the garden with shrubs and flowers. One of the villagers showed considerable ability, whereupon Jenner took him to a 'Musick Meeting' at Gloucester. Indeed, as far as we can gather, he led the happy life of the perfect country doctor."

His fame continued to spread. Diplomas, honours, and addresses were awarded to him to the number, according to Baron, of forty-seven. The freedom of the City of London and of five other cities in the kingdom was presented to him. He received an honorary degree from the University of Oxford. He was made physician-extraordinary to the King. One great distinction was his unanimous election as a Corresponding Member of the National Institute of France; later he became one of its Foreign Associates. One interesting tribute came from the Indians of North America, to whom Jenner had sent his book. The chiefs held a meeting to thank him, and in their reply said:

"We shall not fail to teach our children to speak the name of Jenner, and to thank the Great Spirit for bestowing upon him so much wisdom and so much benevolence. We send with this a belt and a string of wampum in token of our acceptance of your precious gift; and we beseech the Great Spirit to take care of you in this world and in the land of Spirits."

Such was the gratitude of mankind to Jenner that he attained an influence throughout the world such as had never been acquired before or since by a private individual. His name was enough to obtain the release of some Englishmen imprisoned by Napoleon and by other monarchs. Those who travelled abroad were able to dispense with passports if they took a certificate by Jenner. The European inhabitants of India gave him £6,000 in their gratitude. Many medals were struck in his honour and many statues set up. Of his various portraits that by Hobday was considered the best, and by the great generosity of Dr. W. S. A. Griffith it had been presented to the Royal Society of Medicine. On looking at Hobday's portrait no one would be surprised to learn that Jenner was liable to apoplexy. His first attack took place in 1820, his last and fatal attack on January 26th, 1823.

"Usually," said Sir W. Hale-White in conclusion, "when a really great discovery is made it is attacked by ignoramuses, fools, knaves, and cranks. In their day they had their fling at Jenner, but I have not alluded to them, for time and Jenner's fame have cast them into obscurity, where they had better stay. Nor have I given any proofs of the efficacy of vaccination; this has been done over and over again. . . . Rather have I tried to delineate the quiet, retiring country doctor, fond of poetry, music, and painting, beloved by those who knew him, quite unspoilt by fame such as has fallen to very few, a great naturalist, the friend of Hunter, a man who would have been known as a pioneer pathologist if he had published his observations, who by patient thought and observation, extending over many years, arrived at a discovery which not only told us how to banish one of the greatest scourges of mankind, but the principle of which has since been applied so successfully to other diseases."

Sir ANTHONY BOWLY proposed a vote of thanks to Sir William Hale-White for his address. Without entering too deeply into statistics, Sir William had made plain the ravages of small-pox in the pre-vaccination era. At a time when the population of England was only about seven millions the deaths from small-pox were said to amount to 44,000 a year. It was evident also from the way in which Jenner's discovery was acclaimed in all countries that the disease must have been extraordinarily prevalent almost all over the world. Sometimes, when he looked at pictures which illustrated society beauties of 150 years ago, he thought there was not much to be said for their features; but the explanation probably was that the population was so largely pockmarked that almost any woman who had an unsullied complexion was distinguished among her sisters, and, given passable charms, ranked as a beauty. Sir William Hale-White had alluded very briefly to the fact that the British army was spared small-pox in the late war. One of the striking things in the medical history of the war was that there was hardly a zymotic disease which did not make its appearance at one time or another in one part or another of the war area of France and Belgium; but there was only one case of reputed small-pox, and that turned out not to be small-pox at all. When the North Midland Division came out to France it was discovered that it included 8,000 unvaccinated men. These men had come from areas, like Leicester and Derby, where there had been much antivaccination propaganda, and the authorities had a good deal of anxiety before these men were put into the line. It was supposed that the order for vaccination might give trouble, but actually there was none; it was put to the men that it would be assumed by the command that anybody who was afraid of being vaccinated was afraid of fighting; whereupon all the men were vaccinated. Pasteur was born a month before Jenner died; it seemed as though one great spirit had handed on the torch of science to another great spirit; and the greatness of mind of a great man was brought out in Pasteur's statement that to Jenner and not to himself should be given the credit for the discovery of the attenuated virus. It was at Pasteur's request that the name of "vaccine," instead of some new name, was given generally to the matter introduced in preventive inoculations against other diseases.

Dr. R. J. REECE, C.B. (Senior Medical Officer, Ministry of Health), seconded the vote of thanks, and referred to the fact that the Section of Epidemiology and State Medicine, of which he was president, awarded a Jenner medal on occasion to distinguished epidemiologists. Dr. Reece mentioned that his father was vaccinated by Edward Jenner himself.

The vote of thanks was accorded by acclamation.

### THE JENNER MEMORIAL MEDAL.

THE Jenner Memorial Medal here illustrated was founded by the Epidemiological Society at a meeting held on May 15th, 1896, one hundred years and one day after the date on which Edward Jenner performed his first vaccination. The desire of the society was to commemorate a discovery attended with such brilliant results in the direction of preventive inoculation and to promote epidemiological research.

The award of the medal was not to be restricted to British subjects. An appeal was made to the profession to contribute to the cost, and subscriptions were received from all parts of the world. The medal was designed by Mr. Allan Wyon, F.S.A., under the advice of a committee, of which Sir Shirley Murphy was president. On the obverse of the medal is a three-quarter face portrait of Edward Jenner, with the inscription "Edward Jenner, M.D., F.R.S., born 1749, died 1823," and on the reverse a representation of the earth,

such as is engraved on the diplomas of the society, surrounded by the following inscription: "Centenary of Vaccination Celebrated 1896. For Work of Great Merit. Epidemiological Society of London. Venienti Occurrite Morbo." The name of the medallist and the date of the award are inserted on the rim of the medal. Since the Epidemiological Society has been merged in the Royal Society of Medicine the medal has been bestowed on the recommendation of the Section of Epidemiology and State Medicine.

The persons the pre-eminence of whose work in the prevention and control of epidemic disease has been recognized in this way are: 1898, Sir William Henry Power, K.C.B., F.R.S.; 1902, Professor A. Laveran; 1912, Sir Patrick Manson, G.C.M.G., M.D., F.R.S.; 1921, Sir Shirley Murphy, K.B.E., F.R.C.S.; 1922, John C. McVail, M.D., LL.D., F.R.F.P.S.G.

### THE JENNER RELICS.

Mr. C. J. S. THOMPSON, of the Wellcome Historical Museum, kindly placed on view a collection of relics and exhibits connected with Jenner. They included many articles of much personal and historical interest. Among personal belongings there were Jenner's walking-stick, eyeglasses, snuff-box, seal with crest, medicine cabinet, cupping glass, vaccine points cut from a quill, lancets, visiting book, note-book, and prescription book. The walking-stick has at the top the old-fashioned cavity for camphor, protected by a perforated screw lid. There were also medals (one presented

to Jenner by Sacco), diplomas, addresses, holograph letters, and portraits. Two locks of his hair were preserved—one, at 55 years old, dark brown, the other, taken at his death, mixed with grey but by no means white. Neither seemed to correspond very closely with the colour of hair in the Hobday portrait exhibited in the lecture hall. Many old books relating to small-pox and vaccination were on

view. His own works of course were among them, and included both editions of the *Inquiry*, the first dedicated to Dr. Parry of Bath, and the second to the King. Other writers represented were Dimsdale, Haygarth (his *Sketch of a plan to exterminate the small-pox*), Aitken, Willan, Moore, Ceely, and Bousquet. The coloured caricatures and cartoons of the early controversies made a large display, and illustrated the old predictions about the human countenance being changed by vaccination into the visage of a cow, and the new and undreamt-of diseases produced by cow-pox.

The exhibition was particularly rich in illustrations of the day-to-day appearances of the development and decline of the vaccine vesicle. Among them was a copy of the plate in Aitken's little book which was sold in thousands and helped to teach the profession the characters of the vaccine vesicle as distinguished from the "mother pustule" of small-pox inoculation with which they were already familiar. The exhibits included the original Kirtland plates lent by Dr. G. W. Collins, who, between thirty and forty years ago, found them on an old bookstall. They were reproduced in the Jenner Number of the *BRITISH MEDICAL JOURNAL* in 1896, and for convenience the Wellcome Exhibition has placed the reproductions in framed cases so that the whole course of vaccinia and inoculated variola can be contrasted from beginning to end. The differences between the two processes are so great as to be unmistakable.

The Jenner relics and exhibits shown at the house of the Royal Society of Medicine have now been removed to the Wellcome Historical Exhibition, 54a, Wigmore Street, where they will remain on view for a time, along with many articles which were too bulky for conveyance to the special display on the occasion of Sir William Hale-White's address.

THE JENNER MEMORIAL MEDAL: FOUNDED 1896.

## MOTOR NOTES FOR MEDICAL MEN.

BY H. MASSAC BUIST.

## THE SCOTTISH MAJORITY MOTOR SHOW.

THE Majority Exhibition promoted by the Scottish Motor Trade Association, which was opened by the Duke of York at Kelvin Hall, Glasgow, on January 26th, is, of course, not so representative as those in London or Paris, because the only building available is quite inadequate to serve the purpose. The English and French displays are chiefly manufacturers' exhibitions promoted to afford an opportunity of meeting agents and motor traders from all quarters of the globe. By contrast the Scottish show is primarily a display for the purpose of enabling agents to meet their clients. Hence relatively few manufacturers have taken stands, though the exceptions include Arrol-Johnston, Argyll, Bean, Beardmore, Clement-Talbot, Citroën, Daimler, Darracq, Humber, Lanchester, and Vulcan. There are even two London coachbuilders, each of whom has taken a stand—namely, Barker and Co. and Windover; both display large cars, such as Rolls-Royce and Daimler types, equipped with their special town carriage coachwork. For the rest, the well known manufacturers prefer to be represented on the stands of their various Scottish agents. In some cases this is an advantage, as instance the wide variety of Wolseley, Sunbeam, Chevrolet, Vauxhall, Crossley, Overland, Humber, Standard, Hillman, Austin, Citroën, and other popular types of vehicles illustrated in notable variety by reason of one or other of the leading agents in practically all the big Scottish centres being appointed by these firms; each is showing some particular type. In this manner one Scottish agent is able to assist another.

Even so, however, the space problem is very acute despite the cutting down of the circulating avenues and the ingenious use of odd corners of the building. The reason is not surprising. Apart from the eminently international character of the exhibits, they are not confined merely to passenger cars and accessories for them, but embrace, besides, the largest lorries and the smallest motor cycles. The result is a wide recognition of the fact that, though the temporary building, which is little better than a war time shed, provides greater accommodation than any pre-war exhibition building either in Glasgow or in Edinburgh, nevertheless it is wholly inadequate to the purpose of Scotland's motor exhibition. There is therefore afoot a movement to the end that the Glasgow Corporation should erect on the present site of a building that shall be worthy of the country and which shall give the facilities so urgently needed for the promotion of various trades in an age in which it is becoming increasingly gainful to promote annual exhibitions of the wares produced by the leading industries.

## CHIEFLY CONCERNING THE GAELIC INDUSTRY.

For the visitor to the London motor shows in November there is nothing new in the present exhibition, which closes at Kelvin Hall, Glasgow, on the night of Saturday next, February 3rd. Nor are all the novelties introduced in London to be found there. On the contrary, the display represents approximately half the new classes of vehicles seen in London. Nevertheless, a better selection it would have been almost impossible to make. There are complete novelties in chassis and body construction, such as the Lancia-Lambda model displayed in Kelvin Grove. The Scottish passenger car industry, too, is well represented on various stands by Arrol-Johnston, Argyll (introducing a new 11.4-h.p. single-sleeve valve engine model), Beardmore, Galloway, and Rob Roy cars. One impression the visitor gets is somewhat unexpected—namely, that a greater proportion of the exhibits at this show than at either London or Paris consists of the larger middle size, and even of the largest cars. It is not to be inferred from this, however, that the motor trade in Scotland is concerned in any less proportion with the newer small car movement than is that in the south. It is merely that, having a limited space at disposal, agents for given builders prefer rather to show the most impressive vehicles of those makes in their space than the smaller standardized types. For one thing, this gives a greater element of variety to the display because, generally, the more expensive cars are available in chassis form, whereby the individual coachmaker is enabled to present new ideas in bodywork. Many of the leading agents in Scotland came

into the motor business because they were old-established coachbuilders. For the rest, undoubtedly buyers in Scotland are no less interested than those in London in the evolution of small cars standardized with bodies complete. In this connexion the advent of the standardized 11.4-h.p. Citroën chassis, with which the Sabará was crossed, with British-built bodies for passenger road service, is proving of interest. In a larger class, but low in price, is the 23.8-h.p. Treasury rating Dodge car shown on Stand 44 by Messrs. John Croall and Sons, the Edinburgh agents, this being one of the four most remarkable types of cheap cars made by the American industry. The particular examples shown take the form of a five-seater saloon, and of a touring type. But the average medical man will be more interested in the £375 all-steel Dodge coupé; I made trial of it lately, and it proved a quite extraordinary car on the through drive, alike for traffic and in climbing rises. It has three speeds forward; but in practice two only are used, because one invariably starts on the second gear and passes almost immediately into the direct drive if the engine is warm. The electrical engine starter on this car is capable of turning the crankshaft in spirited fashion, with the result that there is no difficulty in getting the engine going in cold weather. The accommodation provided by the coachwork, and the completeness of the equipment, as well as the finish in the matter of window furnishings, and so forth, will repay study on the part of the medical man wanting one of the larger middle sized classes of coupé. It is not a small car, but a full scale one, though the price is more akin to that of the small classes.

## MISCELLANEOUS EXHIBITS.

Dealing in alphabetical order with the exhibits, and omitting the names of the stands on which the various examples are to be found, one notices that the overhead-valve engine Gwynn-Albert types, including the 8-h.p. 2.3-seater and the 11.9-h.p. all-weather models, figure in various parts of the building, as do examples of the 18-h.p. 6-cylinder overhead-valve engine Armstrong-Siddeley type, which has made the most striking performance in R.A.C. certified trials of any vehicle during the last twelve months, the Dewar Trophy having been awarded in respect of one of these performances. Of entirely new cars introduced at Olympia, the 18.50-h.p. 6 cylinder overhead-valve engine Aster chassis is notably low in price, and is the first type made by a firm of over a score of years' experience of specializing on engine production; hence the exhibit is exciting considerable interest. The Austin series is attracting attention by reason of the price of the 12-h.p. and of the 20-h.p. types, and of the novelty of the 7-h.p. two-seater. The Bean doctor's coupé is appealing to business men, too. It is a very serviceable, handy little car with pliant suspension and four speeds forward, the body accommodation being amply large enough for those of more than average stature, and the controls being easy and on the normal side of the driver—namely, the right. The low price of the 6-cylinder Buick models, and the great improvements made in the coachwork this year, are matter of favourable comment, as is the extraordinary value for money provided in the Chevrolet proposition. The new 12.14-h.p. four-seater Crossley is welcomed as bringing this make within a lower purse range than hitherto, a remark which also applies to the introduction of the new 16-h.p. and 12-h.p. Daimler 6 cylinder models, which are represented with special coachwork on quite an extraordinary number of stands.

## NEW TYPES AND FAMILIAR MAKES.

De Dion Bouton and Renault, who from early days have done perhaps more than any other makers, certainly on the Continent, to make motoring a practical proposition for medical men, bring forward their newest models, which are both reduced as to price and, in the former case especially, developed mechanically along lines that bring them quite up to date. The way in which these makers have stood hard use in the past is a great point in recommending them to notice on the present occasion. The very interesting Enfield-Allday car, which made a great reputation by its performances, alike in the hands of the public and in competition, last year is regarded as an outstanding example of the efficient small car class. The Hillman, a pioneer of British small cars, makes a favourable impression by reason of the new 11-h.p. types, numerous represented in Kelvin Hall, being equipped with excellently designed all-weather bodies. The pioneer of the cheap 4-cylinder water-cooled British cars, Humber, this year introduces engines with part overhead and part side

valves; the 11.4-h.p. and the 15.9-h.p. 4-cylinder models are supplemented by a popular 8-h.p. type marketed at £275 complete. By reason of its sweeping series of victories in competition this year, as well as the prices and long proved wearing qualities, the 10/15-h.p. and the 15/20-h.p. Fiat models are proving a great attraction; while the new 6-cylinder type with front-wheel brakes and overhead-valve engine is regarded as a pioneer design of the period and a moderate-priced proposition among the large cars. In the last class the Napier town carriage and the latest Rolls-Royces constitute outstanding features of the exhibition.

The reduction in price of the 12 h.p. Rover standardized coupé as developed since last season makes it a very attractive proposition; the 8-h.p. model is now introduced with a dickey. The bodywork of the Standard car, a specialty of which is the amplitude of the accommodation, including length of leg room, is being commented on favourably. The increase in the engine size of the 14-h.p., overhead-valve, 4-cylinder Sunbeam renders it even a more remarkably lively car than it was last year, when it had no rivals, while it is proportionately as cheap to buy and economical to run. The new 14-h.p. side-valve engined Vauxhall, now in production, is very interesting; with Princeton touring body the price is £595 only, complete.

A novelty to the Scottish motorist is the 14-h.p. side-valve engined Wolseley car, which is to be described as a family carriage, having the same class of chassis as the luxurious 15-h.p. overhead valve engined type. The former is very cheap at £525 complete. Likewise the reduction of £90 in the price of the 10-h.p. overhead-valve engined model of this make brings it within the purse range of a class hitherto unable to consider it.

Take it for all in all, therefore, this is an eminently satisfactory exhibition, and one which has so far proved of great service to those interested in motoring north of the Tweed.

## England and Wales.

### CENTRAL MIDWIVES BOARD.

At the meeting of the Central Midwives Board for England and Wales held on January 25th, with Sir Francis Champneys in the chair, charges against two midwives were considered. One was cautioned and put under probation for three and six months' reports, and the other was removed from the roll and prohibited from practising in any capacity in connexion with childbirth. Communications were read from the Queen Victoria's Jubilee Institute for Nurses and from the Ministry of Health announcing the re-election, as representatives on the board, of Miss Rosalind Paget by the former institution and of Miss Haydon and Miss Le Geyt by the Ministry.

Business dealt with by the Standing Committee included the following resolution from the local supervising authorities for the county of Southampton, Surrey, Ipswich, Great Yarmouth, and Southend-on-Sea:

That the Central Midwives Board be urged to consider the desirability of making a rule prohibiting the application or administration by a midwife of any drug (for example, pituitrin or ergot) other than a simple aperient, before the birth of the child, except under the direction, in each case, of a registered medical practitioner.

It was agreed to reply that the Board has always declined to schedule drugs except in so far as stated in Rule E19, and sees no reason to depart from its practice in this respect. A communication was read from the Public Health Committee of the Bethnal Green Borough Council calling attention to the fact that midwives are apparently allowed to perform the minor operation of stitching the perineum without calling in medical aid, and expressing the opinion that midwives should not be permitted to perform this operation. In reply to this the Board stated that it has already expressed the view that any case of ruptured perineum which requires stitching is a case of "serious" rupture within the meaning of Rule E20 (3).

### THE LIVERPOOL MEDICAL INSTITUTION.

The annual meeting of the Liverpool Medical Institution, at which the report of the council and the treasurer's accounts were received, took place on January 25th. The total number of members and associates was stated to be 459, which was larger than in any previous year; deaths and resignations numbered 22. It was noteworthy that there was a considerable increase in the number of recently-qualified

men and women who had joined the Institution. The financial statement was agreed to be satisfactory, notwithstanding the increased expenditure in maintenance. The Endowment Fund, instituted in 1920, which remained permanently open for additions to the funds of the Institution by donation and legacy, amounted to £4,523. Reciprocity had been effected between the library of the Institution, the medical library of Liverpool University, and that of the Tropical School of Medicine, so that members could make use of all three libraries. Dr. Thomas Clarke and Mr. Robert Craig Dun were elected vice-presidents; and the following were elected members of council: Drs. A. Douglas Bigland, Robert A. Hendry, H. Leith Murray, G. F. R. Smith, R. G. Wills, and Frederick P. Wilson, to fill the six vacancies. With the object of bringing the Institution into closer relationship to all permanent correspondents were appointed by the council to the same number of districts in and around Liverpool.

### THE LIVERPOOL CITY CORONER'S REPORT.

During the past year 1,453 cases were reported to the city coroner of Liverpool, inquests being held in 938 cases. Suicides numbered 70, which was the highest number recorded since 1897, when it reached 73; gas poisoning was the method adopted in 13 cases. In 17 non-suicidal cases accident was found to be the cause of death; 10 accounted for 10 deaths only, less than half the number in 1921. In 1899 the coroner's record of deaths from excessive drinking numbered 242, and during the past eight years the number of similar deaths had very considerably diminished. In the past twenty years the diminution of deaths from suffocation of children (overlying) has been remarkable. Before 1898 these cases averaged 180 a year; in 1921 only 9 cases came before the coroner, and in 1922 there were 12. As a rule the cases were quite unconnected with alcoholic indulgence, and it would be a matter of interest to ascertain in all such cases whether status lymphaticus was the cause and what the condition of the thymus was. Inquests were held on the deaths of 39 newly born children, and fatal street accidents to the number of 69 came before the coroner.

### MANCHESTER ROYAL INFIRMARY.

In the annual report of the Manchester Royal Infirmary the Board of Management directs special attention to the finances, pointing out that annual subscriptions for the past year have been increased by £1,275; actually £1,784 new money was obtained by the canvassers and collectors, but against this sum had to be set withdrawals in consequence of death or other causes. The total ordinary income amounted to £88,037, and the total extraordinary income to £11,332; the total ordinary expenditure amounted to £110,540, and the total extraordinary expenditure to £11,295. The total ordinary income of the Barnes Convalescent Hospital, Cheshire, amounted to £5,397, in addition to the contribution by the Royal Infirmary of £6,352; the total expenditure for the year amounted to £11,749. The income of the Royal Infirmary, with its Central Branch, and the Barnes Convalescent Hospital, excluding legacies and donations for endowment, fell short of the necessary amount by £12,465, and it has been necessary to realize some of the capital available for general purposes. The Infirmary received £10,775 on account of the apportionment of the Government grant of £500,000 to the voluntary hospitals of Great Britain. The enlarged activities of the Committee of the Hospital Sunday Fund resulted in a very appreciable increase in the sum allotted to the Infirmary during the past year, and the creation of the Manchester, Salford, and District Joint Committee of Hospitals and Saturday Fund Representatives was an important step towards the systematic development of collections from working men by way of deductions from wages. An agreement, which was arrived at last April, recorded the determination of the hospitals and the Saturday Fund to work together in order to raise funds to be apportioned on defined and equitable terms. Contributions by patients were £615 less during the year; the decrease is attributed to the prevalent and prolonged unemployment. Contributions from approved societies, on the other hand, made their first appearance in this report. It will be remembered that an audit of the funds of approved societies disclosed a very material surplus, and a portion of this surplus became available for distribution to the voluntary hospitals. The amount received in respect of the maintenance of pensioners showed a large reduction, and it is stated that next year the

amount from this source will be negligible, as practically no pensioners are now being sent for treatment in the Infirmary. When the new infirmary was opened in 1908 accommodation for x-ray work was provided in the basement for what was then a comparatively small department; its growth during the past fourteen years justified the decision to provide more room, and two handsome donations made it possible for the department to be re-established, with the most modern equipment, in what was known originally as the Teaching Block. The Board of Management acquired during the year from the Committee of the Manchester and District Radium Institute the research laboratory installed when the institute was accommodated in the Infirmary. Funds are in course of being raised for a new home for nurses, which, when completed, will accommodate 200 persons; the cost, it is estimated, will be approximately £100,000.

## Scotland.

### VETERINARY SCIENCE AND PUBLIC HEALTH.

Dr. WALTER ELLIOT, M.P., Parliamentary Under Secretary to the Scottish Board of Health, delivered an address, entitled "Some aspects of veterinary science in relation to public health," at the annual meeting of the Scottish Metropolitan division of the National Veterinary Medical Association at Edinburgh on January 24th, with Mr. W. W. Peggie, the president, in the chair. Dr. Elliot said that during the war the veterinary profession of Great Britain was responsible for the transport overseas of fifteen million living animals. That no epizootic had attended so great a movement of animals showed how far veterinary science had gone in grasping the lessons of bacteriology and putting them to practical application. While human medicine was turning very largely to the preventive side, in veterinary medicine, so far, cure had bulked more largely than prevention. The economic loss from animal diseases, resulting in rise in price to the consumer and the weakening of the public health in this country from the excessive cost of the fuel food needed to maintain energies, was one of the immediate aspects in which veterinary science touched the public health of the country. In the twenty years before the entry of live animals was prohibited in this country pleuro-pneumonia and foot-and-mouth disease killed off 800,000 animals, and in the twenty years subsequent only 2,000. That was a triumph for preventive medicine, and a triumph for veterinary science cogently applied by means of legislation.

### GLASGOW STUDENTS' INFIRMARIES DAY.

In aid of the infirmaries and hospitals of Glasgow the students of Glasgow University and of most of the colleges of the city organized a fancy dress procession on January 23th. The procession eventually broke up into collecting parties, which spread over the whole of Glasgow and its suburbs, to form another procession later in the day; in the evening three dances were held. A magazine entitled *Ygorra Special* was published, which consisted mainly of contributions in prose and verse reprinted from the *Glasgow University Magazine*. These many methods of raising money proved highly successful, the total of the day's collection amounting to over £6,800.

### GREENOCK EYE INFIRMARY.

At the forty-second annual meeting of the Greenock Eye Infirmary on January 25th it was stated that the trustees were strongly of opinion that greater facilities for the treatment of eye diseases were still required, and that it was necessary to initiate a building scheme which would bring the Eye Infirmary up to modern requirements. A scheme for the extension of the Infirmary at a cost of £1,950 had accordingly been framed. During the past year the number of patients attending the dispensary for the first time was 4,001, and the subsequent attendances amounted to 9,411; the daily average was 64.4 patients for the 203 days on which the dispensary was open. Accidents occurring principally in the engineering and refining industries, had been treated. In the minor department 217 cases were treated, an increase of fifteen.

### CENSUS OF SCOTLAND, 1921.

#### County of Forfar.<sup>1</sup>

The county of Forfar, north of the Firth of Tay, had on the census day a population of 281,417, but this included the city of Dundee, separately reported on. Excluding Dundee, the county inhabitants numbered 116,413. In the decennium there was an apparent decrease of 11.7 per cent., but in reality the decrease was only 2.2 per cent., the difference being due to extension of the boundaries of Dundee several years ago. The male decrease has been 3 per cent. and the female 1.6. From 1801 to 1881 there was a continuous increase, but in the last forty years the total has fallen from 126,121 to 102,737, the fall including the transfer of population to Dundee. Exclusive of Dundee there are seven burghs in the county, the largest being Arbroath (19,496), Montrose (10,979), and Forfar (9,587). The urban population has appreciably diminished since 1881, an exception being Carnoustie, a golfing resort. The rural population is 42,639, and has slightly increased since last census. The parishes number no fewer than 53. Excluding Dundee, the proportion of females to males is 117.8 to 100; the average age of the male population is 30.6 and of the female 33.8. Of children under 15 years, 88.3 per cent. had both parents alive, 6.6 per cent. had lost their father, 3.5 per cent. their mother, and 0.6 per cent. both parents. Of males aged 15 and upwards, 41.3 per cent. were single, 52.3 married, and 6.4 widowed or divorced; the corresponding percentages for females were 45, 42.9, and 12.1. Gaelic speakers numbered 323, all bilingual. Again excluding Dundee, the average number of persons per house was 4, and the number of persons per 100 windowed rooms was 115. Since 1861, when there were 163 persons per 100 rooms, there has been a steady diminution in density. Living in one roomed houses there were 4.9 per cent. of the population, in two-roomed houses 28.1, in three-roomed houses 29.4, and in four roomed houses 11.5 per cent. Of males aged 12 years and upwards, 90 per cent. were in remunerative occupations, and of females 36.2 per cent. Of occupied persons 19.8 per cent. were employed in agriculture, 15.4 in textile industries, 10.5 in personal service, and 8.7 each were working in metals and in transport and communication.

#### County of Inverness.<sup>2</sup>

This central Highland county has, with its islands, a larger area than any other county in Scotland, and is exceeded in England only by Yorkshire. Its total population, however, is only 82,455, its maximum of 97,799 having been reached in 1841, since when the tendency has been irregularly downwards. Of the total population 29.2 per cent. is burghal, and 70.8 extra-burghal. Inverness—the capital of the Highlands—had a population of 20,944, an intercensal decrease of 5.7 per cent.; the only other burghs are Fort William (1,913) and Kingussie (1,272). Of the total population of the county, 27,924 was insular, this being less than at any previous census. The largest island, Skye, has 11,031 inhabitants, or less than half its population in 1841; the next largest are Harris, 3,918; South Uist, 3,235; North Uist, 2,579; Barra, 2,180; and Benbecula, 1,116. The total number of inhabited islands is 46, of which 10 (including two lighthouse islets) show an intercensal increase. At the census the average number of persons per house was 4.83, and per 100 windowed rooms 101, being a steady improvement since 1851. Of the total population, 2.1 per cent. lived in one-roomed houses, 15.9 in two-roomed, 25.4 in three-roomed, 14.9 in four-roomed, 12.6 in five-roomed, and 9 per cent. in six-roomed. The proportion of females to 100 males was 109, the average male age being 32.4, and female 34.5. Of children under 15 years 7.7 per cent. had lost their father, 4.4 their mother, and 1.8 both parents. Of the male population aged 15 and upwards, 51.4 per cent. were unmarried, 43 married, and 5.6 widowed or divorced, the corresponding figures for females being 47.9, 38.5, and 13.6 per cent.

Speakers of Gaelic in this county numbered 39,892, or 48.4 per cent. of the population, against 70.9 per cent. in 1881, when the first Gaelic census was taken; by 54 per cent. of the population Gaelic is the only language spoken. In the islands Gaelic speakers prevail much more than on the mainland, and 16 per cent. of the island population speak Gaelic only, the percentage being very high in childhood.

<sup>1</sup> Thirteenth Census of Scotland, Volume I, Part 17. Price 8s. 2d. post free: H.M. Stationery Office, 23, Firth Street, Edinburgh.

<sup>2</sup> Vol. I, Part 18. 7s. 2d. post free. Obtainable as above.

69.2 in the age group 3 to 4, and 22.9 in the age group 5 to 9 years. Of males aged 12 years and upwards, 87.7 per cent., and of females 27.2 per cent., were in remunerative occupations. Of occupied persons in the county of Inverness and its islands 27.6 per cent. were employed in agriculture, 15.2 in personal service, 9.2 in transport and communication, and 7 per cent. in commerce. Fishermen numbered 4.2 per cent.

## Correspondence.

### SMALL-POX AND VACCINATION IN THE PHILIPPINES.

SIR,—Will you permit me to congratulate Dr. J. C. McVail upon his instructive analysis of small-pox and vaccination in the Philippines, published in the *BRITISH MEDICAL JOURNAL* (January 27th, p. 158)? With your permission and indulgence I should like to add something about the period which immediately followed the departure from those islands of the Spaniards in 1898.

As a medical officer with the United States troops I served in the Philippines up to 1903, and I returned for a second tour in 1910, and left again in 1913. I only mention these personal items to bring out a point which I regard as very important in this connexion—namely, that vaccination was very successful in the Philippines when performed properly and conscientiously. Before the American occupation there had been an annual small-pox mortality of something like 40,000. I well remember that the natives regarded the disease with about as little fear as we did an ordinary cold, and that in our campaigns we constantly found instances without the slightest attempt having been made at isolation; also, the proportion of natives one saw with pock-marked faces was painfully large.

In 1902, the backbone of the insurrection having been practically broken, and when medical officers could be spared for the work, an energetic vaccination campaign was inaugurated which extended throughout the principal islands. At the same time all discovered cases were isolated.

How well this work succeeded—and this is the true practical demonstration of the value of vaccination in the Philippines—is shown by the statement that "the 19,000 deaths in 1903 fell to 9,000 in 1904, to 4,000 in 1906, to 3,000 in 1910, to 1,000 in 1911, and to a few hundreds annually from 1912 to 1916." Can anyone doubt that this remarkable decline was due to the campaign of vaccination inaugurated in 1902?

Upon my return to the Philippines in 1910, instead of finding almost every other native pock-marked, as I had in my first tour of duty, I rarely saw a face deformed by these unsightly scars among the younger generation—that is, among those who were of the age to have profited by our early vigorous vaccination onslaughts.

But how are we to account for the sudden jump in 1918 to 14,574, and in 1919 to 45,873 deaths? The Rockefeller Foundation survey now being made will no doubt elucidate the matter, but one is inclined to think that in considerable measure changed conditions of government will prove the key to the solution of this mystery. As the islands became more peaceful there was a gradual transfer of government into the hands of the natives themselves, and a consequent withdrawal of Americans, and with them practically all their medical men, military and civilian. The supervision, direction, and execution of vaccination and other sanitary undertakings were assumed by the Filipinos themselves, and one is inclined regretfully to conclude that the work was no longer of a sufficiently high standard to continue the successes obtained by their predecessors.—I am, etc.,

H. M. COREX.

Manchester, Jan. 30th.

### NYSTAGMUS.

SIR,—Dr. J. A. Wilson kindly refers (January 27th, p. 171) to a small paper of mine on miners' nystagmus, but he has misunderstood me when I speak of a predisposition to the disease in children. I was not referring to children occurring in children, but to the miners who will develop later under appropriate conditions in those predisposed to the complaint.

It is important to distinguish between the various forms of nystagmus.

I. *The vibratory form*, in which the movements have the same to and fro velocity; there are two main varieties:

(1) The rotatory form, from two and a half to six oscillations a second, which, as far as I know, only occurs in miners' nystagmus.

(2) The slow wandering searching movements seen when the eyes are blind or nearly blind.

II. *The resilient form*, in which a comparatively slow movement occurs in one direction, followed by a rapid jerking movement in the opposite direction, or in some cases by a rapid oscillation. This form is seen in some nervous diseases such as disseminated sclerosis, Friedreich's ataxia, as well as in vestibular nystagmus.

Finally, nystagmus may be acquired or congenital (that is, beginning at any rate in very early life); in congenital nystagmus—for example, that due to albinism—the patient never complains of the movements of objects.

Now miners' nystagmus is acquired, is always of the vibratory form, and may be either rotatory or oscillatory in character. It is rarely found except among pitmen, hewers, deputies who have been hewers, and stonemen working underground. But it has been found in ceiling paperers, accountants who use very large ledgers, and others who work in a very good light. My personal feeling is that the exciting cause is, as the late Dr. Snell was always urging, maintaining the eyes for long periods in a strained position (usually obliquely upwards), and that deficiency of light is only a contributory cause. Since only a small percentage of pitmen acquire the disease, and since these, after recovering from all their symptoms on leaving their underground work, will, in my experience, always have a recurrence of the disease on their return to hewing, I contend that ultimately the disease depends upon an idiosyncrasy or a predisposition with which they are born. One may call it a congenital inadequacy of the fixation centre to withstand long-continued strained positions of the eyes, but I have laboured this point elsewhere.—I am, etc.,

A. S. PERCIVAL.

Newcastle-upon-Tyne, Jan. 28th.

### TURPENTINE OR LEAD POISONING A CAUSE OF PUNCTATE BASOPHILIA.

SIR,—In a letter in your columns (January 27th, p. 170) Dr. F. C. Eve refers to my paper on "The blood as guide to early diagnosis in lead poisoning." His experience does not enable him to dispute or corroborate the truth of my statements, which are inferences from facts stated in the paper. As, however, he suggests that the presence of turpentine (or its substitutes) seriously interferes with diagnosis of plumbism in painters, his eminence as a physician demands consideration of this point.

Dr. Eve states, "It is not generally known that inhalation of turpentine vapour can also cause basophilia indistinguishable from that produced by lead." But surely no one expects that basophilia produced by lead is different from that produced by any other poison or toxin. We cannot distinguish enlargement of the spleen due to malaria from that due to typhoid, but this in no way lessens the importance of splenic enlargement as a sign of disease. As I tried to explain, basophilia means that something is acting injuriously on the marrow, and if this is lead the urine will contain a trace of the metal even in the absence of corroborative symptoms.

In his last sentence Dr. Eve asks for information as to the effect of turpentine vapour in varnish workers, so I infer that he knows nothing personally of its effect in man or animals but only in vegetables. In short, he derives his information from a Blue Book wherein it is stated that in experiments on animals "basophilia staining was found with both turpentine and white lead, and even the animals exposed to zinc oxide and zinc sulphide showed the presence of a few basophils in the blood." In accepting unreservedly this uncorroborated statement, Dr. Eve has forgotten that there is no evidence whatever that it applies to man under working conditions. Till Dr. Eve has investigated the point among the varnish workers at Hull I venture to hope he will accept my statements.—I am, etc.,

ROBERT CRAIN.

London, W., Jan. 28th.

### THE DIAGNOSIS OF INDEFINITE MASSES IN THE BREAST.

SIR,—The paper by Mr. Duncan Fitzwilliams in your issue of January 20th (p. 94) is such a valuable contribution to the only reliable method of dealing with this type of case—namely, by close co-operation between the clinician and the pathologist—that I venture to make some remarks thereon from the point of view of the histologist.

The problem before the pathologist is not only to diagnose established carcinomata and to estimate the degree of malignancy thereof, but to detect the precancerous stage of chronic mastitis. Now, this cannot be done by any "few minutes" method, even when this is available, as it fortunately seldom is. Careful fixation and the examination of serial paraffin sections are essential for accurate work.

For the purpose of this note I have examined my own records of the last 600 specimens of breast tissue sent for histological examination, and I find that 24 per cent. were examples of chronic mastitis, 10 per cent. precancerous stages, 44 per cent. established carcinomata, 2 per cent. sarcomata, and 20 per cent. non malignant conditions other than inflammation; nearly all of these were fibro-adenomata, a condition which, as far as we know, does not become cancerous. In other words, in about one-third of the cases which would be roughly diagnosed as chronic mastitis definite precancerous changes were seen.

The main problem for solution in consultation seems to me to be what to do with the histologically precancerous breast. Is there a stage in which removal of the breast alone suffices? Many surgeons, to my knowledge, cut the Gordian knot by performing the radical operation, and it is difficult to raise any valid objection to this from the pathological point of view. They say, in fact, that nowadays the resulting disabling is so slight with the modern technique that it is better to be on the safe side and remove the lymphatic area also. Is this the accepted surgical teaching? Were the advantages of the preliminary operation advocated by Mr. Fitzwilliams, followed by histological examination, more commonly recognized in general practice, I feel sure that there would be fewer deaths from cancer. The practitioner who takes upon himself to decide by inspection and palpation alone that a lump in the breast is not malignant incurs a very great responsibility.—I am, etc.,

A. KNYVETT GORDON, M.B., B.Ch.Cantab.

London, W.C., Jan. 29th.

### OCCIPITO-POSTERIOR PRESENTATIONS.

SIR,—I have read with much interest Mr. Comyns Berkeley's address on "Some practical difficulties in obstetrics and gynaecology," as published in the *JOURNAL* of January 20th (p. 89), and, while I am in entire agreement with most of it, there is one part with which I entirely disagree—namely, his treatment of occipito-posterior presentations.

The treatment he seems to advocate as a routine is manual rotation of the child, and, while one must respect the views of so eminent an authority, I am strongly of opinion that such treatment is both unnecessary and risky. The picture he draws of cases that are not diagnosed or are not rotated manually is to my mind entirely wrong, and its dangers are greatly exaggerated. My experience of these cases is just the reverse, and I believe that they do far better if left alone as far as possible. They are usually associated with uterine inertia, and I believe that the proper course is to treat this by giving sedatives, etc. After a period of rest the uterine contractions become strong; this causes flexion of the head and the occiput rotates forwards. During a fairly extensive experience of such cases in recent years, both in private practice and as medical officer to an institution, I cannot remember a single case in which rotation has not taken place. At times I have applied axis-traction forceps when the head has been down in the vagina and, if it has not rotated previously, it has done so as soon as traction has been applied.

With regard to rupture of the perineum also, my experience does not agree with Mr. Comyns Berkeley's, for I have found that it has been less frequent in such cases than in occipito-anterior cases, probably owing to the fact that the child's head has undergone greater moulding and that the maternal soft parts have had more time to relax. Although such cases frequently last two or three days, I have no experience of children being born in a state of asphyxia or suffering from intracranial injury.

Manual rotation requires skill and is not without its dangers, and I have little doubt that, were it generally adopted, it would mean a considerable increase in the number of cases of sepsis.

Occipito-posterior presentation in my experience occurs in about 20 per cent. of all cases of midwifery, and therefore to advise as a routine practice a procedure which involves such obvious risks is a matter for grave consideration.—I am, etc.,

Wolverhampton, Jan. 28th.

W. R. SOMERSET.

### TREATMENT OF TUBERCULOSIS OF THE CERVICAL GLANDS.

SIR,—In your issue of November 4th last (p. 858) Dr. John Fraser, in his paper on treatment of tuberculous cervical glands, evidently assigns a most unimportant part to x rays, and would limit this agent to the lymphoid type only. Even Sir Herbert Waterhouse does not favour this treatment apparently, and states that he has never seen a cure by x rays. However, many writers elsewhere are quite convinced of the superiority of such irradiation in treating almost every case to other methods of treatment. Thus Boggs, who has had a very extensive experience in this direction (*Amer. Journ. Med. Sci.*, July, 1921, clxii, 90), sees good reasons for coming to the following conclusions:

1. Radium and the x ray will cure more cases of tuberculous adenitis than any other method. Roentgenotherapy will cure over 90 per cent. of these cases.

2. Surgical treatment is always contraindicated in every case of tuberculous adenitis.

3. Those who still hold to radical operation will find the responsibility hard to shoulder with the ever-increasing recognition of the fact that tuberculous adenitis can be cured without it.

4. Hard fibrous nodules following roentgenotherapy seldom contain any tuberculous foci, but it may be permissible to remove these through a small incision as with a foreign body.

No doubt the failures referred to in the *BRITISH MEDICAL JOURNAL* may be attributed to rays of insufficient penetration or faulty technique. My own experience is limited, but a patient treated by myself on July 19th last is instructive. Glands had been removed from her neck two years previously, and these had recurred on both sides. As the result of a single irradiation they almost disappeared, although a small superficial gland has since appeared. She has now had a single larger dose and it is expected that she will be free from further trouble. Incidentally the ugly scar due to the operation has become soft and supple and scarcely noticeable.—I am, etc.,

Melbourne, Dec. 20th, 1922.

H. FLECKER, F.R.C.S.

### HOSPITAL POLICY.

SIR,—Dr. C. E. S. Flemming's letter (January 20th, p. 129) calls for brief reply. Patients are sent to hospital, not because they cannot be accommodated or maintained at home, but because they cannot be treated there. If while in hospital they are able to pay only for that which they must anyhow obtain when at home, and which it is no function of the staff to provide, their claim upon the latter is not impaired. If, however, they can, in addition, pay something for treatment, the position is radically changed, and lay boards will readily appreciate the distinction, which is not "arbitrary" but logical. What these boards assuredly will not recognize is an "honorary staff" who reject a pauper because he is too poor, and a man who, while he is in hospital, scrapes together a shilling a week, because he is too rich. Would Dr. Flemming himself approach any hospital board with such a proposal? So far from being more defensible and acceptable than our plan, as he maintains, no evidence is produced that a single member of the Council or Hospitals Committee, save Dr. Clarke, whose position is exceptional at Leicester, has dared to bring his policy before the lay board of his own or of any general hospital, or would stand any chance of success if he did. Why should we be called upon to do what they lack either courage or skill to achieve themselves? Let them set the example, and report results, or abandon a vain project.

As regards the bookkeeping difficulties anticipated by Dr. Flemming, he is presumably unaware that the policy I advocate has been working, with the aid of almoners, quite successfully in the Bristol hospitals for a year and a half. Further, at Leicester, where the plan he commends has, in the absence of almoners, been equally successful, the bookkeeping entailed is far more complicated than at Bristol, because contributors to the staff fund are there graded into three classes, each of which furnishes a different percentage to the fund.

In fact, their plan is in no way more simple than ours. It is evident, therefore, that the fears of Dr. Flomming in regard to bookkeeping are as groundless as those of the Council in respect to manipulation of funds. I have not so far encountered any objections to our plan which will bear examination, whereas the dangers attaching to his proposal are so obvious and insurmountable that scarcely anyone has attempted to overcome them.—I am, etc.,

Chichester, Jan. 28th.

G. C. GARRATT.

### PENAL DISCIPLINE.

SIR,—Since I have been travelling and have missed Sir Wemyss Grant-Wilson's somewhat belated criticisms (BRITISH MEDICAL JOURNAL, December 16th, 1922) on points in my book, *Penal Discipline*, perhaps you will be good enough to allow me this somewhat belated, but earliest possible, reply.

Sir Wemyss's first point is to contradict my statement that the Borstal girls were put in irons. He does not appear to know that the use of the instrument of restraint known as the "body belt" is officially and rightly classed as irons, as the prisoner's hands are restrained in ordinary steel handcuffs. My figures are from the official returns of girls put in irons, and the body belt used during my service was mainly of my own design. This form of restraint was suggested by me some years ago, as a modification of the more severe forms of restraint which were applied to violent women in local prisons. The ordinary handcuffs, worn for hours, or days, or nights, are a cruel form of restraint, especially for stout women and girls. They contract and fix the chest, make deep breathing difficult, and certainly never calm an excited woman, who has every need of sufficient oxygen. They render sleep almost impossible and compress the axillary and mammary tissues painfully. They give rise to filthy scenes.

The belt is put on loosely round the hips so that the hands in the handcuffs passed through the belt hang by the sides. The belt can be rotated through a quarter of a circle, and one hand can just reach the mouth, so that prisoners can attend to their own needs. They cannot, however, injure themselves or anyone else. This restraint is, however, provocative of more excitement and is not to be defended in any conditions now prevailing in prisons. I discouraged its use on the dreadful cases we used to have in local prisons, and many matrons learnt to do without it. Its use had decreased in local prisons almost to vanishing point during my service, when it was adopted *de novo* in Borstal institutions. But for a number of years Borstal institutions also managed without it.

I have never seen any change in the character of inmates committed either during or after the war which could possibly have made this form of restraint necessary or advisable. The majority of girls who broke out did so under the irritation caused by report and punishment. So well is this form of outbreak known to occur among those who suffer from hysteria, as also the tendency to self-mutilation, that it is the rule, after an award of punishment, to return the prisoner to a cleared cell. This form of outbreak hardly ever happens now in local prisons, and ought not to happen in a Borstal institution.

As regards the girl restrained eight times who later "committed suicide" by setting fire to herself at Rampton, although Sir Wemyss is "asking for it," I am not the person to tell your readers her history. Why does he not do so himself? I will merely remind him that she was a girl of inferior surroundings and education to other inmates and that she had had a very good record in a reformatory school. She showed no signs of hysteria until she came under penal discipline. When under penal discipline she became unmanageable, she was certified as "feeble-minded" or its equivalent, and sent to Rampton. Here she committed the act which caused her death. She is an outstanding instance on my side of the argument, which I refrained from quoting myself.

Girls who have led "irregular lives" are not necessarily excitable under detention, if suitably treated, and I cannot agree with Sir Wemyss Grant-Wilson that their restraint is ever a "necessity."

In the sense that I have used the word "repression" in my book it stands for an unconscious process. It cannot be "learnt" by any of us. The *direction of instinct* is a very different matter, can be learnt, and does not lead to nervous explosion. But it can never be taught under penal

discipline, nor through restraining an hysteric as an angry and dangerous animal when once repression has done its work.—I am, etc.,

Küssnacht, Zürich, Jan. 22nd.

MARY GORDON.

### FEES IN COURT CASES.

SIR,—In the London papers of January 19th a case is reported in which a medical witness, on entering the witness box, stated that he had been subpoenaed but had not had his fees guaranteed. Counsel immediately asked him: "Are you a Scotsman?" and later the judge is reported to have said: "He seems to me to be about as greedy a doctor as I have come across. He must have his fees."

One cannot be long in practice without feeling the inconvenience of court cases which interfere with one's work and generally involve some pecuniary loss also. Unless the doctor is to be exploited, there are many points in the legal side of medical practice which must be learnt, although not taught at hospital; and it is surely very unfair that invidious remarks should be made in such a case as this, in which *the fees had to be allowed*, and in which the witness was correct in asking that they should be, immediately on entering the box.—I am, etc.,

Sevenoaks, Jan. 24th.

J. FINLAY ALEXANDER.

### VITAMIN CONTENT OF CERTAIN PROPRIETARY PREPARATIONS.

SIR,—May I be allowed space for a brief reply to the letter by Miss K. H. Coward and Professor Clark in your issue of January 27th (p. 171)? I would like to repeat that what I wrote was that their article in your issue of January 6th was "apt to produce a misleading impression" in regard to Virol. This it does, in my view, by classing Virol with preparations whose advertised claims in regard to vitamin concentration were not supported by the results of their investigation, and by the concluding statement that "no advantage is to be gained by trying to obtain these substances in the form of drugs"; no such attempt having been made in the case of Virol, which is a food.—I am, etc.,

London, Jan. 29th.

ARTHUR E. CANNEY,  
Managing Director, Virol Limited.

### STATE HOSPITALS.

SIR,—I am anxious to profit by all *bona fide* criticism of Poor Law hospitals, so I have been considering the remarks of Viscount Cave as reported briefly in your issue of January 27th (p. 169). He speaks of State hospitals "where there was no one, apart from the patient's relatives, whose duty and pleasure it was to see him from day to day, to watch over his comfort, and give him that personal attention which meant so much to a sick person." Can you suggest what official of a general hospital Lord Cave had in mind?

Connected with this hospital there are visiting and resident doctors, a matron, assistant matrons, sisters, nurses, probationers, chaplain, and welfare visitors. It is the duty of these officers to give the patients "constant, thoughtful daily care," and I think they perform their duty fairly well. In addition members of the board and various philanthropic ladies pay frequent visits and contribute to the comfort of the patients.

I cannot find the blank in the staff that Lord Cave refers to.—I am, etc.,

HENRY H. MACWILLIAM,  
Senior Medical Officer, Walton Infirmary, Liverpool.  
Liverpool, Jan. 29th.

At the International Exhibition of Photography, Optics, and Cinematography, to be held at Turin in May and June next, prizes will be given for various kinds of films—among others, films of scientific subjects.

The announcement is made from Canada that 2,715 claims have already been received for the prize of 100,000 dollars offered by Lord Atholstan of Montreal for the discovery of a cure for cancer; claims have come from forty-one different countries. It is pointed out, however, that claimants must satisfy a recognized medical faculty or leading medical society in his or her own country first that there is some scientific basis to justify the experimental investigation of the professed cure, and that any cases said to have been successfully treated were in fact cases of cancer.

## Obituary.

JOHN WILLIAM BALLANTYNE, M.D., F.R.C.P.E., F.R.S.E.,  
Physician Royal Maternity Hospital, Edinburgh, and Ante-natal  
Department; Lecturer on Midwifery and Gynaecology to  
Women Students, University of Edinburgh.

THE death of Dr. J. W. Ballantyne in Edinburgh on January 23rd came as a shock to his colleagues, few of whom knew of his illness. About ten days previously he had been compelled to take to his bed with one of his periodic attacks of influenza, but there were no symptoms to cause any anxiety until the day before his death. Very suddenly he was seized with violent abdominal pain, which laparotomy within two hours proved to be due to a ruptured appendix. Never very robust in the last few years, and weakened by ten days of illness, the scales were from the first heavily loaded against his recovery, and he died within twenty-four hours of the operation. In him the world loses a man posterity will regard as one of the makers of modern medicine, and the Edinburgh school one of its most renowned ornaments.

John William Ballantyne was born in June, 1861, at Eskbank, Midlothian, where his father was a nurseryman and seedsman. After a period at Bonnington Park School, Peebles, he passed to George Watson's College, Edinburgh, where he completed his school education. He passed through the medical curriculum at Edinburgh University, and graduated M.B., C.M. in 1883, winning as a fitting crown to a distinguished undergraduate career the Buchan Scholarship in Midwifery and Gynaecology. This scholarship carried with it the privilege of acting as house-surgeon to the University Ward for Diseases of Women, then under the charge of Professor A. R. Simpson, and the association with Simpson thus begun was to prove one of the strongest formative elements in Ballantyne's life and career. From the Royal Infirmary he passed to the Royal Maternity Hospital during Simpson's term, and after some months spent in visiting the medical schools of Berlin, Munich, and Göttingen he was appointed by the Professor as both his private and his university assistant. Ballantyne became by examination M.R.C.P. Edin. in 1887,

and in the following year was elected to the Fellowship. In 1889 he graduated M.D. with a thesis on "Some anatomical and pathological conditions of the newborn infant in their relation to obstetrics," for which he was awarded a Gold Medal and the Gunning-Simpson Prize in Midwifery.

After five years as University assistant Ballantyne ventured forth into the Extramural School as lecturer on midwifery and diseases of women in the School of Medicine of the Royal Colleges. For twenty-six years he taught faithfully and successfully both men and latterly women students, until in 1916, on the admission of women to the University classes in medicine, he was called back to the academic fold as lecturer on midwifery to women students. This appointment he held with acceptance to the time of his death.

In 1920 Ballantyne was appointed assistant physician to the Royal Maternity Hospital, and four years later he succeeded his friend, the late David Berry Hart, as physician. In this capacity he served for the full period of fifteen years, retiring in 1919. Meantime in 1901 the Hamilton Bed was endowed in the hospital for the "purpose of the treatment of the diseases peculiar to, or accidental during, pregnancy." (Previously only women whose confinements were imminent were admissible to the hospital.) This event, which may be taken as marking the

beginning of that care of the expectant mother which Ballantyne did so much to develop and popularize, was the response on the part of a generous and anonymous donor to Ballantyne's urgent and telling plea published in this JOURNAL. Before long the single bed had to be expanded to a ward, as doctors and nurses and even patients themselves gradually in increasing numbers realized the value of pre-maternity care. Ballantyne fostered this part of the hospital work with enthusiasm, and organized a system by which women in the "district," suffering from diseases incident to pregnancy, were visited by specially trained nurses, and if necessary brought into the hospital. The work developed rapidly, and in April, 1915, the first pre-maternity and infant welfare centre was started in the hospital under the name of "Infant and pregnancy consultations for expectant mothers." In 1917 the ante-natal department of the hospital came under the administrative and financial care of the municipality, and Dr. Ballantyne was appointed "extra-physician in charge of the ante-natal department." Two years later a department

for the treatment of venereal disease in pregnancy and labour was started, and to the charge of this also Dr. Ballantyne was appointed by the city authorities. In addition to these purely professional duties in the Maternity Hospital, Dr. Ballantyne interested himself deeply in all its affairs. For two years (1908-10) he acted as its honorary secretary, and subsequently became secretary to the medical board with a seat on the board of management, thus forming a direct link between directors and staff.

The promise of the researches embodied in his M.D. thesis matured in the publication between 1892 and 1895 of his two volumes on *Diseases of the Foetus*. Inevitably he found himself, in his search for causes, thrust back to the study of earlier stages of ante-natal life. Embryonic conditions were therefore dealt with in his *Teratogenesis* (1897), and included in his classic volumes on *Ante-natal Pathology and Hygiene* (1902-4). In all this Ballantyne was doing work of a pioneer type in that he not merely collected laboriously and summarized all the work previously done on the subject, but attempted to produce order out of chaos and establish a really scientific classification of, and nomenclature for, the innumerable varieties of embryonic and foetal deformities and diseases.

In 1902 the Royal College of Physicians of Edinburgh recognized this in the award to him of the Collen Prize "for the greatest benefit to practical medicine in the previous four years."

Elected a Fellow of the Edinburgh Obstetrical Society in 1883, Ballantyne passed through the various offices of secretary, editor of *Transactions*, and vice-president, and was elected to the presidential chair in 1906-7. From the first he was a prolific contributor of scientific papers, and a fluent participator in the discussions of the Society; to his industry it is indebted for the complete index of the *Transactions* of its first twenty-one years, by which means many interesting, valuable, and historical papers have been rendered more accessible.

Ballantyne's writings soon rendered his name familiar to workers in midwifery and gynaecology, not only in his own country, but all over the world. This was seen in the honours which he received. He was invited to act as examiner in Aberdeen University in 1895-99, in Edinburgh University 1901-5, and at his death he held similar appointments in the Universities of Glasgow and Liverpool. He was an honorary Fellow of the Glasgow Obstetrical and Gynaecological Society and of the American Association of Obstetricians and Gynecologists; an honorary member of

DR. J. W. BALLANTYNE.

[Scan Watson, Edinburgh.

the American Child Hygiene Association and of the *Sociedade Scientifica Protectora da Infancia* (Brazil). In 1910 he was chosen Vice-President of the Section of Obstetrics and Gynaecology at the Annual Meeting of the British Medical Association in London. Besides the professional activities, Ballantyne took an active interest in all that affected the welfare of his school. He was one of the first to see the value and importance of post-graduate teaching, and was convener of the committee to which the establishment of the now famous post-graduate courses in Edinburgh was attributable. He was also an active working member of the General Council of the University.

The British Medical Association held an important place in his interest, and characteristically he took his full share of the local work as a member of the Branch Council and of the Executive Committee of the Division. For some years up to his death he had acted as Edinburgh correspondent to this JOURNAL, and in other ways he contributed to it to an extent which only the Editor could reveal. Those, however, who could recognize his unsigned writings will recall with pleasure many of his short annotations on, for example, "Medical Terms in the New English Dictionary," and on many other antiquarian and philological points touching upon medicine.

Ballantyne's industry was phenomenal. Probably a week-day never passed without his writing something for publication, and his total output would do credit to a journalist who had no other interests or occupation. He was the author of some ten scientific volumes, including besides those already mentioned *Diseases of Infancy*, 1891; *Essentials of Obstetrics*, 1901; *Essentials of Gynaecology*, 1906; and *Expectant Motherhood*, 1914. He edited two issues of Green's *Encyclopaedia Medica*; of the same publisher's *Dictionary of Medicine*; and of the *Quinquennium of Medicine and Surgery*. He founded and edited during the two years of its existence the journal *Teratologia*. He acted as subeditor for Scotland of the *International Clinics*, and in addition to all this he published between four and five hundred articles in medical and other journals.

Moreover, his writing was habitually on a high level of literary excellence. His sentences were poured out with not merely fluency and ease of style, but at times with the cumulative force of a torrent, sparkling with a freshness and variety of apt and illuminating imagery that is most unusual in medical papers. Doubtless this was due in no small measure to his extraordinarily wide reading and the possession of a wonderfully retentive memory. His mind was a positive encyclopaedia which he could, as it were, open at the desired page on a moment's notice. This extraordinary breadth of culture marked him as the natural successor to Berry Hart in the office of librarian to the Royal College of Physicians. This office he adorned, and he enjoyed to the full the privilege of supervising the affairs of that fine collection of old and new books. His own private library was also a reflection of his mind and of the immense scope of his knowledge. His rooms were packed with books on every conceivable subject—medicine, history, biblical study, ethics—and a noble collection of the classics of many languages and of different eras. He is said to have had some eight editions of Boswell's *Life of Johnson*—a man whom he resembled in his omnivorous reading and insatiable thirst for knowledge. Lighter literature he did not eschew either, and when in the vein he could write admirably in a facetious style. Perhaps the most outstanding example of this is his inaugural address to the Edinburgh Obstetrical Society in 1906 on the "Future of obstetrics," in which he humorously recorded an imaginary conversation with the President of the Society in 1940 (its centenary year). Like a positive Jules Verne, he describes many imaginary changes in the obstetrical world of that day, several of which are now accomplished facts or well on the way to be so. So successfully did he combine instruction with light humour that this paper became one of the best known of his writings, was translated into several foreign languages, and proved a most effective instrument of propaganda in favour of ante-natal care.

This almost uncanny power of prevision was one of Ballantyne's striking characteristics. By nature and temperament he was a scholar rather than a practitioner. He lived in the main outside the dust and turmoil of the arena of practice, and so was perhaps enabled to see farther and more clearly into the future than those who are harassed and burdened by the cares of practice. Worldly advancement, moreover, was not his ambition: his aim was service to his fellows, and in that he spent himself lavishly.

Ballantyne's greatest claim to fame and remembrance will

undoubtedly prove to be his pioneer work in seeking to establish ante-natal pathology on a scientific basis, and still more the practical application of that in the foundation of clinics for expectant mothers. It is instructive to observe how rich a harvest in practical benefit to humanity is now beginning to be reaped from the apparently arid and stony fields in which for so long he ploughed a lonely furrow. For years when he first began to preach the value of ante-natal supervision and care he was as "a voice crying in the wilderness," but by sheer persistence he won a hearing, and a great deal of the modern development of midwifery along preventive lines is the direct outcome of his labours.

No account, however brief, of Dr. Ballantyne's life could possibly be regarded as even remotely adequate which did not touch reverently upon that aspect of his life which bulked so largely in his own mind—namely, his religion. At an impressionable age he was, as we have seen, brought into close association with Professor A. R. Simpson, for whom he conceived a boundless admiration and affection. Simpson's well known evangelicalism could not fail to make a deep and lasting impression on such an ardent and faithful disciple. Moreover, this was the period of Henry Drummond's brief but brilliant lay ministry among the students of Edinburgh University, and Ballantyne was one of those who early fell under the spell of his vivid spirituality. It is, then, small wonder that he became a man of deep and sincere religious life. His faith was childlike in its perfect simplicity and in its immanence in all the innumerable activities of his life. It produced in him a beautiful charity of disposition, which enabled him to suffer long and yet remain kind, and it endowed him with the quiet confidence and endurance in the face of a lack of recognition in his early years, which we can now see to have been necessary to the fulfilment of his destined work. In a man of such colossal industry it was inevitable that his religious life should manifest itself in activity as well as in quiet, contemplative study. Only a few of the outlets for this activity can be mentioned. During his tenure of office at the Royal Maternity Hospital he conducted a short service for the patients every Sunday afternoon; and he loved nothing better than addressing Brotherhood meetings. He served his church also loyally in more ordinary paths. For many years he was an elder in St. George's U.F. Church under his cherished friends, the late Dr. Alexander Whyte and Dr. John Kelman, and he even found time to act as session clerk. For many years he was a director of the Edinburgh Medical Missionary Society, and from 1907 to 1912 was its president, taking an active share in its work and contributing liberally to its support. Much of his time and thought was occupied by the cause of foreign missions, and he served on various committees of the U.F. Church dealing with them. It is credibly said that he never allowed a Sunday to pass without writing a letter of encouragement and friendship to one or more foreign missionaries. The unselfish thoughtfulness of such an act speaks volumes.

In 1889 Dr. Ballantyne married Miss Emily Rosa Mathew, daughter of the late Mr. George Mathew, Worsted Lodge, Cambridgeshire. No children were born to them, and his wife predeceased him in 1914.

On Friday, January 26th, he was buried in the beautiful Dean Cemetery, Edinburgh, in presence of a very large number of friends and colleagues, representatives of the multifarious interests of a life of ceaseless service.

R. W. J.

We are indebted to Sir HALLIDAY CROON, emeritus professor of midwifery in the University of Edinburgh, for the following tribute to Dr. Ballantyne:

In common with my colleagues I received a very great shock on hearing of the unexpected death of my old friend, John William Ballantyne, as the result of gangrenous appendicitis. He was one of my earliest pupils in the Extra-mural School here, and he and I have been associated together in the Obstetrical Society, in the Maternity Hospital, and for the last seventeen years as colleagues in the University. Very early in his career he identified himself with the department of obstetrics, becoming assistant and university tutor with Sir Alexander Simpson, and to this branch of medicine he had devoted himself exclusively ever since.

All through his life the striking feature about him has been his endless perseverance and concentration on anything he undertook, and this is conspicuously borne out in the characteristic enthusiasm with which he devoted himself to the somewhat obscure and unremunerative work in teratology.

on which subject his writings and communications are exhaustive; indeed, his enthusiasm carried him so far that he published a journal on teratology. The whole question of monsters was an open field to him, and his minute and accurate knowledge of their classification and anatomical relation was absolutely unique.

It is to his endless credit and to that of the school to which he belonged that he laid the foundations of ante-natal pathology, and he stood out, *facile princeps*, as the greatest living authority on this subject; as a matter of fact he developed the whole department and brought it nearly to perfection in Edinburgh. He had entire charge of the ante-natal clinic in the maternity hospital, and the devotion, care, and time that he bestowed on that clinic only those who were his immediate colleagues can ever know. In the successful development of this clinic he was frequently brought into very delicate relationships with his colleagues, and his infinite tact and judgement were recognized by all of us in the hospital.

His powers of application and devotion to work were colossal. My association with him during the last seventeen years was very close and intimate, as we met every day, lecturing as he did to the women students, who were entirely under his care as far as obstetrics were concerned, and we shared class assistants, tutors, servants, diagrams, museum, and apparatus in common. During all those years we never had a misunderstanding or friction of any kind whatever, and I shall never forget our daily interviews in the University retiring room. Of these causeries I retain a vivid recollection. They were not always medical, being more often political, social, or religious; but this thing I will say, that I never remember Ballantyne saying or hinting an unkind thing of any human being. No one could be in daily association with him as long as I was without recognizing that he seemed removed from the petty cares of this world, and in his company one felt lifted into higher environment. He never cultivated practice very much, and was at his best always in his library, where he spent long hours daily. His literary output was stupendous. Apart from his original work in teratology and ante-natal and obstetrical research, the mere editing of two editions of the *Encyclopaedia Medica* was an undertaking sufficient to have occupied half a lifetime.

He brought permanent and world-wide reputation to the Edinburgh School to an extent that is not realized either by the public or the practitioners of medicine, but I can safely say that no foreign visitor ever came to Edinburgh who did not wish specially to be introduced to and know Ballantyne personally. He led a very simple life, very seldom dined out, was a member of no club, and social entertainments did not appeal to him very much. It is characteristic of him that at one time he was a great smoker of strong and unattractive tobacco, and one day while walking with a friend was taxed on the subject; he threw his pipe and pouch of tobacco over the dyke and never smoked again.

His integrity of character and abounding humanity were the special features of his life. *Integer vitae scelerisque purus*. He shone specially as a secretary: his minutes were always monuments of accuracy and care, and to that work he grudged neither time nor trouble. Religion was to him a natural secretion, an integral part of his being; like the circulation of the blood, it performed its function without attracting any special attention on his part to itself.

Ballantyne was a really learned man; he had intellect, energy, and literary skill, and these gifts he loyally and ungrudgingly gave in the service of his school of medicine and mankind. I shall ever remember him as a kind and conscientious colleague and a considerate friend.

Dr. B. P. WATSON, professor of midwifery and diseases of women in the University of Edinburgh, has been good enough to send the following:

The medical profession the world over mourns the death of Dr. J. W. Ballantyne. By his voluminous writing he was known to everyone who has any pretence to special knowledge in midwifery and gynaecology, and his persistent efforts on behalf of the expectant mother and his constant advocacy of adequate ante-natal care brought his name prominently before every practitioner. When he began his work in ante-natal pathology he was regarded by many as a pedant engaged in researches which could never have any practical clinical application. It is one of the happiest thoughts of him, now that he has gone, that he lived to see his work appreciated at its full value, both from the purely scientific standpoint and from the point of view of its practical application. I know

that this was an intense satisfaction to him, and that he felt it was ample reward for his many years of hard and otherwise unremunerative scientific work.

To those of us who knew the man as well as the scientist his loss is great indeed. In his younger days he was a keen golfer and tennis player, but these sports he sacrificed for the sake of his work, and for many years he found his only relaxation among his books. His library was large; it contained the best books in all branches of literature, and he knew every one. There was no apparent arrangement, but he could put his hand on any book or hunt out any article at a moment's notice. Many of us, when engaged in research, have availed ourselves of his unique knowledge of medical literature. It did not seem to matter how obscure the reference, or how long since the article appeared—Ballantyne would be sure to know of it and be able to produce it.

He was loved by his students, and by none more than the women, whom he taught first in the Extramural School and latterly in the University. After they graduated many of them corresponded with him and put before him for solution the difficulties they met with in practice or in the mission fields of India or China where so many of them went. He loved to think that so many of his students had taken up missionary work, for he had that simple faith which made him throughout his life a true Christian. His relations with his colleagues were always of the pleasantest nature. I shall never forget his kindness to me personally. I knew him first as my teacher in the Maternity Hospital, and his were the first congratulations cabled to me on my appointment to the chair of midwifery in Edinburgh. The Edinburgh Medical School can ill spare such a man at this time, for he was one of those who was recognized everywhere as a leader in midwifery, and so helped to maintain the tradition of which we are so proud.

Dr. JAMES YOUNG, assistant physician, Royal Maternity Hospital, Edinburgh, with which institution Dr. Ballantyne was so long connected, writes:

The death of J. W. Ballantyne has removed from us one of the noblest of minds and one of the masters of modern medicine. Ballantyne's claim to recognition amongst the makers of medicine rests on two solid foundations—his investigations on ante-natal pathology and his pioneer efforts to direct attention to the value of ante-natal supervision. It is probably right to say that he was the founder of the science of ante-natal pathology, and his two large volumes remain to the present day the classics in this subject. The dominating passion of his later years had its natural origin in these preliminary scientific labours, for by them he was led to a recognition of the immense wastage of child life that could be prevented by proper supervision of the carrying woman. His was an imagination that kindled into flame at the thought of big service to his fellows. During the past twenty years his life was illumined by this thought, and his untiring advocacy by speech and writing of the need and place of the ante-natal clinic carried conviction almost as much by his transparent sincerity and high sense of duty as by the brilliance of his exposition. For long he faced apathy and even opposition, but the efforts of his detractors only served to increase his zeal, and beyond the days of temporary hostility and indifference he kept a vision of the permanent assurance of his work.

Of Ballantyne as a man it is difficult for those of us who loved him to speak adequately. I have known him for nearly twenty years, and during the latter part I have grown to value his friendship as one of the richest things in life. Charity, sincerity, and simplicity, linked with a firm religious faith, were the secrets underlying a life of unusual charm and sweetness. I have seen him hurt by unjust criticism, but I have never known him to utter one uncharitable word, and I believe his soul was unable to harbour an uncharitable thought. To outsiders he might seem to possess small vanities, but those who knew and loved him saw them rather as the little self-protections against the world which a heart childlike in its simplicity and more sensitive than rugged had all unconsciously woven round itself.

He was an untiring writer. Much that came from his pen bears the stamp of the master. Much has probably small permanent value and stands merely as the record of a mind teeming with ideas and consumed with the desire of expression. Ballantyne's religion was the driving force of his life. He loved to tell of the help he derived from prayer in any of life's great decisions, and into his work he carried the spirit of the true missionary.

Dr. F. J. BROWNE, who worked with Dr. Ballantyne in the ante-natal department of the Edinburgh Royal Maternity Hospital, writes:

The death of our beloved chief has come as a stunning blow, overwhelming in its tragic unexpectedness. At the moment the sense of personal sorrow and loss overshadows all, and it is difficult to write or even to think of aught else. On Monday morning, January 15th, he had performed a Caesarean section with his usual skill (he had never lost a patient after this operation) although even then he was not feeling well. How little we thought, as he afterwards said his usual cheery "good-bye," that he had gone out for the last time from the department that had meant so much to him, which he had organized and staffed, and of which we know he was so proud. When we think of him it is not yet as the great pioneer of pre-natal care, though we know of his greatness, and had a jealous care for it, confident that the day would surely come when fairly but universal recognition would be his. We think of him rather as he came at his morning and evening visits—enthusiastic, kindly, simple; then his ward round, when no patient was overlooked, but each received an encouraging word; and afterwards the almost daily conference with his staff on matters of administration and details of treatment, at which the suggestions of even his most junior resident were received with consideration; and then those more confidential, because more leisurely, evening talks after the work of the clinic was over for the day. Much was said then that cannot be told. Many were the confidences freely exchanged; wise the advice freely given; but amidst it all there was no unkind or uncharitable word spoken by him, nor would he allow it without gentle reproof in others. For actions or words that appeared somewhat harsh or unkind he invariably sought and found some extenuating circumstance. This, I think, is the memory of those conversations that will most remain. Lately he was much gratified by the appreciation of his work that was shown on many occasions by his colleagues and in the medical press of this and other countries, and about a month ago said to me that it appeared to him now that if he was remembered it would be by his work on ante-natal care rather than by his earlier work in otology.

Those who were most intimate with him are aware how little even all his scientific work and voluminous writings circumscribed his activities and how varied was his interest and profound his learning. He loved old books and rare editions, of which his own library contained many examples. How he found time to indulge these tastes must seem a mystery until it is known that 6 a.m. in winter and summer was a usual hour for commencing work. From then till 10 a.m. was done most of the work of the *Encyclopaedia Medica*, the ninth volume of the new edition of which he had almost completed at the time of his death. Only a few nights previous to his fatal illness I found him at a late visit hilarious as a schoolboy over the parody by Kipling and Graves of the fifth book of the *Odes of Horace*. He could never be prevailed upon to take a holiday, and for the last two weeks we had thought he looked tired. Once or twice, too, he had recently complained that he was feeling the strain of his literary work.

When all this is written, how bald it seems, and how little it expresses the vivid, strong, and varied personality that we were privileged to know! What were his outstanding characteristics as he appeared to us? Simplicity, kindness, intense energy and enthusiasm, cheerfulness, industry, thoroughness. He had the power of eliciting in an unusual degree the affection as well as the respect of those who were privileged with his friendship. To them especially the loss of his guiding hand appears irreparable, but his memory will remain an inspiration. And they believe that he has lit such a torch as shall never be put out.

#### HUNTER F. TOD, M.A., M.D. CANTAB., F.R.C.S. ENG.,

Surgeon to the Ear, Nose, and Throat Department, London Hospital.

We regret to announce the death, on January 23rd, of Mr. Hunter Finlay Tod, the distinguished aural surgeon, at the age of 52, after a long and painful illness gallantly endured. Hunter Tod was the second son of the late Mr. David Tod, J.P., of Eastwood Park and Hartfield, Renfrewshire. He was born in 1871, and was educated at Clifton College, Trinity College, Cambridge, and the London Hospital. He graduated B.A. (with first-class honours in natural science) at Cambridge in 1892, M.A., and M.B., B.Ch. in 1896, and M.D. in 1907. He gained a

surgical scholarship at the London Hospital in 1895, in 1896 he took the diplomas of M.R.C.S. Eng. and L.R.C.P. Lond., and in 1898 became F.R.C.S. Eng. He spent a year on the Continent studying in the special clinics of Berlin, Vienna, Leipzig, and Halle, working for a considerable period under Killian and Jensen in Berlin. After holding the post of resident medical officer at the Throat Hospital, Golden Square, he was appointed surgeon to the throat and ear department of Paddington Green Children's Hospital, and subsequently assistant aural surgeon to the London Hospital.

At the time of his death Hunter Tod was senior surgeon to the ear, nose, and throat department of the London Hospital; he had held this appointment for twenty years, and his term of office had recently been extended for another five years. He was lecturer on aural surgery at the London Hospital Medical College, which owed much to him for his keenness in organizing and improving the teaching of that subject. He was also consulting surgeon to the West Herts Hospital. He was president for the present year, and a former vice-president, of the Section of Otology of the Royal Society of Medicine; and was vice-president in 1910 of the Section of Otology at the Annual Meeting of the British Medical Association. He was formerly examiner in otology at the Royal Army Medical College, and had been a member of the Special Aural Board of the Ministry of Pensions.

He was the author of many contributions to the literature of otology, the published results of his experience of intracranial complications being particularly noteworthy. His excellent little book on *Diseases of the Ear* was issued in the Oxford Medical Manual Series in 1907, and went into several editions; he contributed special sections on "Diseases of the external ear and tympanic membrane" to *Albutt's System of Medicine*, and on "Operations upon the ear" to *Burghard's System of Surgery*.

Hunter Tod was of small size and light build, but had played half-back at rugby football for his college at Cambridge, and, as a student, for the London Hospital. To the end he was excellent company, and his more intimate friends, who knew him affectionately as "Jinks," loved the air of jesting self-assurance which he habitually assumed towards them. He was a man of confident and optimistic outlook and a surgeon of great patience and gentleness. As a consultant his opinion was widely sought and highly valued, and his skill as an operator, particularly in the performance of mastoid operations, was recognized and admired by his colleagues. It has been stated, on good authority, that he was the first surgeon in this country to perform the now everyday operation of true submucous resection of the nasal septum.

He leaves a widow, who is the eldest daughter of Dr. Stanley Rendall, of Aix-les-Bains, and one son and three daughters. A memorial service was held on January 26th at St. Marylebone Parish Church, which was attended by a large number of his colleagues and friends.

A colleague at the London Hospital writes: Hunter Tod was connected with the London Hospital for close on thirty years, having come there as a student on leaving Cambridge. After a short time on the assistant staff he served as senior aural surgeon for over twenty years, and there also he died. He was thus in every sense a "London" man, and his affection for the hospital and his loyalty were amongst the main-springs of his life. His zeal for his own special department was unbounded, and he was tireless in his efforts to extend its scope and promote its efficiency. Indeed, his incessant demands for an increase of beds became almost a standing joke between him and his colleagues when the members of the staff sat in council. Others are more competent to speak of his skill as an operator in his chosen branch; but as one who only came in professional contact with him over cases on the boundary-line between medicine and surgery, the writer can testify to the general trustworthiness of his opinion and the soundness of his judgement. Yet it is probable that he did not always get full credit for his extensive and accurate knowledge. Like one of the characters in *The Wrong Box*, he thought that there was "nothing like a little judicious levity." This humorous way of looking at things, along with a certain flippancy of manner, at times tended to conceal from those who did not know him well his great reserves of clinical experience. But it was just these characteristics which most endeared him to his friends. He derived from his Scottish birth a dry sense of humour and a gift of delicate sarcasm, while his English education had smoothed away the surface asperities apt to be met with in those who come from north

PSYCHOLOGICAL MEDICINE.—Mary R. Barker, S. Blanton, N. H. Clubbala, J. Gifford, G. W. Greene, F. H. Guppy, E. L. Hopkins, P. D. Hunter, P. McLuskie, N. W. Maxwell, N. Roberts, W. D. Sammon, C. E. A. Shepherd.

## Council and Committees.

Dr. W. S. Lazarus-Barlow, Sir John Broadbent, Dr. T. W. Eden, and Sir George Newman were elected Councillors, on the nomination of the Council, to take the places of Drs. Lauriston Shaw, Copeman, Chaplin, and Blacher, who retired by rotation. Dr. Herbert Spencer and Dr. Raymond Crawford were elected members of the Library Committee, on the nomination of the Council, to take the places of the late Sir Norman Moore and the late Sir James Galloway.

## Appointment of Delegates.

Sir William Hale-White and Dr. R. A. Young were appointed as representatives to a conference summoned by the University of London concerning the courses of instruction provided by medical schools.

Permission was granted to the editor of the *Lancet* to reproduce the portraits of certain physicians in a publication intended to celebrate the centenary of that journal.

The President was appointed a delegate to attend the celebration, on June 5th to 7th next, of the 803th anniversary of the foundation of St. Bartholomew's Hospital.

Dr. R. O. Moon was appointed to represent the College at the celebration of the centenary of Jenner by the Académie de Médecine.

Sir Francis Champneys was appointed, on the nomination of the Council, a representative of the College on the Central Midwives Board.

## Lecturers.

The President announced that the Council has appointed Lieut.-Colonel William Glen Liston, C.I.E., M.D., to deliver the Milroy lectures in 1924.

On the recommendation of the President it was resolved that the appointment of the Lloyd-Roberts lecturer be made by the Censors Board.

The Committee of Management reported that Mr. H. J. Waring had acted as Visitor of the Board at the Examination of the Egyptian School of Medicine, Cairo, in January.

## Regulations for the D.P.H.

The Committee of Management presented new regulations for the D.P.H. England, in conformity with the resolutions and rules framed by the General Medical Council, to come into force on January 1st, 1924. The Committee presented a report criticizing the action of the General Medical Council.

The report pointed out that in the new resolutions and rules of the General Medical Council no provision is made for candidates in the army to receive instruction in the duties of a medical officer of health under a sanitary staff officer in the Royal Army Medical Corps having charge of an Army Corps, District, Command, or Division, such as was formerly provided for in the regulations. The report continued:

"The committee have already called the attention of the General Medical Council to the hardship to officers of the R.A.M.C. in being deprived of this opportunity of studying for the diploma, when, at the request of that Council, the Committee expressed their views on the advisability of revising the regulations. Further, it appears that under the new regulations, the instruction under a sanitary officer in India, in the Colonies, and the Colonies will be no longer acceptable, the interpretation of the new rules by the General Medical Council, the whole course of training under a medical officer of health must be given under one and the same officer in one and the same area, and must cover all the subjects mentioned in Section II, paragraph II 4 (a) to (f), and it is improbable that these conditions can be fulfilled elsewhere than in this country. The Committee are of opinion that the new regulations cause a distinct hardship to officers in the R.A.M.C. and to Indian and Colonial doctors, and they recommend that the Royal Colleges should again draw the attention of the General Medical Council to this undesirable aspect of the new regulations."

The report was approved.

## UNIVERSITY OF OXFORD.

The following degrees were conferred in the present term on Saturday, 8th, and Saturday, March 24th. In Natural Science are announced 3th, at Keble College; March 20th, at Merton, Exeter, New, Brasenose, Corpus Christi, and Wadham Colleges.

Robert d'E court Atkinson, B.A., has been elected to a Research Fellowship at Hertford College.

At a congregation held on January 25th, the degree of bachelor of medicine (B.M.) was conferred on D. S. Davies.

A pamphlet of 16 pages entitled "Information concerning the school of medicine, medical degree, and post-graduate medical study and research" is available from the Press and sold by the Clarendon Press, Oxford, price 1s. net. Leaflets of the examinations and the Diploma in Public Health and the Diploma in Tropical Medicine can be obtained by applying to the Dean of the Faculty of Medicine, Museum, Oxford.

## UNIVERSITY OF CAMBRIDGE.

Under the recent arrangement for the interchange of teachers Dr. Friedrich Zscholke, professor of zoology and comparative anatomy in the University of Basle, has commenced a course of

sixteen lectures on the European fauna. The corresponding exchange lectures at Basle will be given next term by Mr. J. T. Saunders, demonstrator of animal morphology. At a congregation held on January 26th the degrees of Bachelor of Medicine and Surgery (M.B., B.Ch.) were conferred on N. G. Thomson.

## UNIVERSITY OF LONDON.

A MEETING of the Senate was held on January 24th, when the Vice-Chancellor (Mr. H. J. Waring) was in the chair. Sir George Newman, M.P., was reappointed representative of the General Medical Council for 1923-24. The meeting was presided over by the Vice-Chancellor.

D.Sc. IN EMBRIOLOGY.—G. S. Sansom, University College, for a thesis entitled: Early Development and Placentation in *Arvicola (microtus) amphibius*, with special reference to the Origin of Placental Giant Cells.

D.Sc. IN PHYSIOLOGY.—G. V. Anrep, M.D., University College, for a thesis entitled: The Metabolism of the Submaxillary Gland.

In some copies of the *BRITISH MEDICAL JOURNAL* of December 30th, 1922, p. 1282, the asterisk did not show against the name of Miss Edith M. Hall, indicating that she had been awarded the University medal in Branch IV (Midwifery and Diseases of Women) of the M.D. examination of the University of London.

## CONJOINT BOARD IN SCOTLAND.

The following candidates have been approved at the examination indicated:

FINAL EXAMINATION.—Medicine: J. S. Bizzett, E. T. Hall, J. J. Mann, J. H. Murray, R. M'D. McKinnon, C. C. L. Spurring. Midwifery: J. S. Bizzett, D. G. Coultis, J. J. Mann, J. H. Murray, C. C. L. Spurring. Medical Jurisprudence and Public Health: J. C. Colvin, D. G. Coultis, J. G. Currie, J. Dey, D. K. Fisher, M. Goldberg, C. M. Hinds, O. ap Vychan Jones, R. F. Kerr, L. A. Moody, W. Melrose, A. Menzies, J. P. T. Mills, J. G. O'Kieffe, G. M. Rose, J. J. du Pré de Roux, R. D. Seogi, H. Sen.

The following candidates, having passed the Final Examination, were admitted L.R.C.P.E., L.R.C.S.E., and L.R.F.P. and S.G.: D. Gold, T. C. H. Neil, C. J. B. Fox, J. M. Crombie, E. Brazao, Annie F. Perry, Hilda Page, Johannes J. Malan, Katherine M. Celan-Jones, B. McLaughlin, J. E. Rodrigo, I. S. K. Bain, et Saled et Gohary Sheir.

## SOCIETY OF APOTHECARIES OF LONDON.

The following candidates have passed in the subjects indicated:

SCIENCE.—G. G. Brown, M. P. Parker, R. F. A. Philpott, H. M. White. MEDICINE.—B. Basuny, H. A. Daly. FORENSIC MEDICINE.—H. J. Adams, B. Basuny, C. S. Laurence. MIDWIFERY.—B. Hart, W. M. Jones, C. S. Laurence.

\* Section I. † Section II.

The diploma of the Society has been granted to Messrs. G. G. Brown, M. P. Parker, and R. F. A. Philpott.

## Medico-Legal.

## AN ACTION FOR NEGLIGENCE.

A CASE of importance to the medical profession came before Mr. Justice Rowlatt and a special jury.

The plaintiff, Miss Coleberd, claimed damages against Dr. P. A. Colmer of Yeovil, alleging negligence in setting a fractured forearm. It was alleged that defendant failed to set the bones in apposition, that he set them out of alignment, and did not take reasonable care to see that they were set so as to unite. In consequence there was marked displacement of the lower fragments, and the bones failed to join properly. An operation subsequently became necessary, at which the bones had to be sawn through and reset with plates and screws. It was complained that Dr. Colmer neglected to make an x-ray examination of the arm, and that plaintiff's recovery had been unduly and unnecessarily prolonged. Compensation for loss of employment, and special damages of £21 18s., were claimed. The defence was that there had been no negligence.

Mr. Rayner Goddard conducted plaintiff's case, and defendant was represented by Mr. J. A. Hawke, K.C., with whom was Mr. G. D. Roberts (instructed by Messrs. Hempsen, solicitors to the Medical Defence Union).

Mr. Goddard, in opening, said it was alleged that by reason of the defendant's neglect of what were in some respects elementary precautions, plaintiff, a young woman of 26 with her living to get, suffered from a broken arm for some three or four months—a much longer period than would have been the case had proper treatment been applied at an earlier date. The accident occurred on June 9th, 1921, and both bones of the left forearm were fractured. Dr. Colmer was sent for, and, after applying a temporary splint, removed Miss Coleberd to his surgery, where he set the arm. There were no complications, and it appeared to be a simple fracture. Altogether she paid sixteen visits to Dr. Colmer, and at the end of the sixth week, when the splint was taken off, it was obvious that the broken bones had not united. The complaint was that he neglected to have an x-ray photograph taken in order that he might see the condition of the bones after the setting. The bones did not unite, and she consulted a surgeon in Yeovil who had the arm x-ray photographed, the girl having then to undergo two operations. She had now a fair arm, although she was unable to do anything like hard work.

Plaintiff's cross-examination denied that she had jolted the arm, and that the arm had been set.

Mr. A. J. Colmer, on to the Bournemouth hospital, stated that plaintiff consulted him and brought x-ray photographs, which disclosed the bones overlapping at the fracture. From his observation they must have been in that position for some three months. Judging from what he found, proper treatment had not been afforded the arm. It was a difficult fracture to set, and in his opinion nothing could have been more helpful than the taking of an x-ray photograph to see that the setting was satisfactory; he regarded that as a routine practice nowadays. When the arm did not mend he thought it amounted to a lack of reasonable care not to have taken an x-ray photograph. He did not agree that Miss Colebird was a bad bone-forming subject.

Mr. Maillie, of the Bournemouth hospital, gave evidence that he did not think the arm had been put straight by manipulation. In his opinion the deformity had only been of one month's duration.

Mr. Hawke, addressing the jury, said it had been suggested that Dr. Colmer did not know his job to the extent expected of the ordinary medical practitioner. He had a large practice in Yeovil, which he had carried on for a great many years, after succeeding his father, and there had never been a breath of suggestion against his professional character or competence. Expert evidence would be called on the question of x-ray examination, also to show that the girl was unusual in her absence of bone-making capacity.

Dr. Colmer gave evidence describing his treatment of the case, and stating that he did not consider an x-ray examination necessary after he had set the arm. The girl's home was ten miles from Yeovil, and he suggested she should be attended by the doctor in her own locality, but she expressed preference to remain under his treatment. On July 22nd he found there had been no union of the bones—the first case of non-union in that position he had had in the whole of his professional experience. The girl was in a bad condition of health, and he prescribed a tonic to improve her general health and bone-making capacity. On August 19th when he again removed the splints the bones seemed to be united, and he told plaintiff what a straight arm she had. He instructed her to keep the arm in a sling, and get some massage treatment. On August 27th the arm was in good condition, but on September 9th, when next he saw Miss Colebird, he found there was a good deal of swelling in the tissue around the seat of the fracture. It suggested to him that there had been some violence. Feeling the bones with his fingers he found they were not in alignment, and he reapplied the splints after putting them in alignment. In cross-examination he denied that plaintiff had ever raised the question of an x-ray examination. There was an x-ray apparatus at Yeovil hospital, but he did not think it necessary to put plaintiff to the expense of undergoing that examination, which would have cost two guineas.

Mr. H. R. Unwin, assistant surgeon to the Yeovil hospital, stated that he examined plaintiff's arm on September 19th in consultation with Dr. Colmer and found it perfectly straight, but there was no union of the bones. He considered the treatment had been correct, but suggested that the ends of the bones should be rubbed together, thus encouraging union. He also agreed with Dr. Colmer that the girl should endeavour to regain better general health before any operation was carried out.

A nurse gave evidence that she was engaged to give massage and did so for eleven days between August 28th and September 8th. During this time she noticed nothing abnormal. On September 9th she got the patient to see her doctor because deformity and swelling had suddenly appeared.

Mr. T. H. Openshaw, C.B., consulting surgeon to the London Hospital, stated that he was the first surgeon to use the x-rays when introduced into this country. It was not usual to take an x-ray photograph of a limb in "this nature. One could get out using the x-rays for examination to advise massage, as Dr. Colmer had done in this case. He saw no reason why Drs. Colmer and Unwin, in consultation, could not find by manipulation whether the bones were straight. If plaintiff had been operated upon immediately she might not have got such a good arm as she had at present. His theory was that she was a bad bone-maker.

Mr. Goddard: Do you say an x-ray examination was not necessary in this case?

Mr. Openshaw: Yes. It would have prevented this case being brought. You would not have a leg to stand on if there had been an x-ray examination by the defendant.

Mr. Richard Warren of Weston-super-Mare, formerly surgeon to the London Hospital and examiner in surgery at the Universities of Oxford and Cambridge, stated that after hearing the evidence he could not criticize Dr. Colmer's treatment in any way up to the time the girl went to the seaside.

His Lordship, summing up after counsel had addressed the jury, said the patient of an ordinary general practitioner was entitled to expect fair skill from her doctor, but not such great skill as one might expect from a specialist in Wimpole Street. The jury must not suppose because this had been an unfortunate case, and there had not been such a cure as in most fractures of the kind, that the doctor ought to be mulcted in damages. If a doctor made a mistake, and it was not due to want of reasonable skill and care, that was a misfortune. One could not expect infallibility in doctors more than in any other professional men. It was for the jury to say whether they thought Dr. Colmer had been guilty of negligence. If they found for the plaintiff it was a case for moderate damages.

After an hour's retirement the jury returned a verdict for the defendant, and judgement was entered accordingly.

## Medical News.

At a joint meeting of the Darlington Division of the British Medical Association and the North of England Branch of the Veterinary Association to be held at the Greenbank Hospital, Darlington, on Friday, February 9th, at 4 p.m., there will be a discussion on tuberculosis in milk. It will not be confined to disease, but will also cover the conditions to which milk is subject before it reaches the consumer. Professor Goffin, the chief veterinary officer for Edinburgh, will put forward the veterinary view, and the medical aspects will be presented by one of the local tuberculosis officers.

The announcement that Sir Richard Douglas Powell, consulting physician to the Middlesex Hospital, will give an Emeritus lecture on Friday, February 2nd, reaches us late. The lecture, which will deal with aortic regurgitant disease regarded specially from a prognostic and life assurance point of view, will be given at 3 p.m.

THE Fellowship of Medicine and Post-Graduate Medical Association has arranged a course of seven practical lecture-demonstrations on certain diseases of children, to be held during February at the Children's Clinic, Western General Dispensary, Cosway Street, N.W., on Tuesdays and Fridays, at 5 p.m. The first on February 13th and the last one on March 6th will be given by Sir William Bayliss and the other five by Dr. Bernard Myers, whose concluding lecture will be devoted to "The nervous child as seen in general practice." The fee for the course is one guinea; copies of the syllabus can be obtained from the Secretary to the Fellowship of Medicine, 1, Wimpole Street, W.1.

THE meetings of the Zoological Society of London for scientific business will be resumed on Tuesday, February 6th, at 5.30 p.m. Attention is called to the great increase in the cost of paper and printing, which renders it necessary that papers should be condensed and limited as far as possible to the description of new results. Dr. R. W. A. Salmund has been appointed honorary radiologist to the Society.

THE Dental Board of the United Kingdom announces that the third series of the prescribed examination under the Dentists Act, 1921, will be held during April next. The closing dates for entries are as follows: for examination at London, March 6th; at Manchester, March 21st; at Edinburgh, March 30th. Notices will be sent to those whose names have been entered on the list of candidates. It is important for those whose names are entered on the list of practitioners of less than five years' standing to bear in mind that there will only be two more opportunities for them to present themselves—namely, April and July of this year. Letters relating to this subject should be addressed to the Secretary for Examinations, 44, Ballan Street, W.1.

REPORTS received from the Red Cross in Russia indicate that there are now some 3,000,000 cases of malaria in the republic west of the Ural mountains. In Georgia one-half of the population are affected, and at the village of Sambourdale, near Tiflis, two-thirds of the total population have died of malaria. Many of the malaria cases are malignant, and the disease is particularly prevalent in the Volga region, where the famine has been so severe, and in the Caucasus. The Russian Medical Aid Committee has received an urgent request for quinine in large quantities, and would be glad to receive contributions addressed to Mr. A. Baker, Treasurer, Medical Aid Committee, 68, Lincoln's Inn Fields, London, W.C.2.

COLONEL R. H. ELLIOT'S book on *Tropical Ophthalmology* has been translated into French by Dr. Coutela of Paris and Dr. Morras of Rabat. The volume is published by Masson et Cie. Dr. Francisco Maria Fernandez has also prepared a Spanish translation, which is published by the Twentieth Century Press, Havana.

THE Royal Society of Medicine announces in our advertisement columns that the William Gibson Research Scholarship for medical women will be awarded in June next to a qualified medical woman selected by the Scholarship Committee. The scholarship is for £250 for two years. Further particulars can be obtained on application to the Secretary of the Society, 1, Wimpole Street, W.1.

Dr. John Craig Crawford and Dr. Josephine Letitia Denny Fairfield, both of the Middle Temple, were called to the Bar on January 25th.

A WINDOW in memory of the late Dr. Hayes Newington has been erected by the members of his family in the Ticehurst Parish Church, Sussex.

SIR ROBERT ARMSTRONG-JONES, C.B.E., M.D., has been appointed a Deputy Lieutenant of the county of London.

A BANQUET was held recently in Paris to celebrate the jubilee of the well known Paris medical journal *Progrès Médical*; Professor Richet presided, and the history of the journal was reviewed by the present editors, Dr. Loeper and Dr. Genty.

THE death is announced of C. P. Goerz, the founder of the firm of optical instrument makers known especially for its field glasses and cameras.

THE firm of William Helnemann announces in our advertisement columns to-day a plan, new to this country, of introducing its medical and surgical publications to country practitioners who, because they reside far from booksellers' shops and medical libraries, have no opportunity of seeing the latest medical books. It will meet also the difficulty encountered by practitioners in towns, owing to the fact that ordinary booksellers are indisposed to stock medical books. The plan is to offer general practitioners the opportunity of seeing the medical books of the firm on approval for a week without any expense to them.

A GIFT of over 100,000 dollars from an American lady, Mrs. Guggenheim, has enabled the Vienna faculty of medicine to open new and well furnished quarters for students of medicine who are unable to work at home owing to lack of fuel and books. A condition of the gift is that absolute freedom from racial and religious prejudice should prevail.

A CONGRESS of Social Hygiene will be held in Paris from December 18th to 23rd, 1923.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 422, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 422, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Artiology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2620, Gerrard.
3. MEDICAL SECRETARY, *Mediscera*, Westrand, London; telephone, 2633, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Itacitus*, Dublin; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate*, Edinburgh; telephone, 4261, Central).

## QUERIES AND ANSWERS.

### INCOME TAX.

"E. C." holds a salaried appointment and has claimed to deduct £25 expended on coaching and university fees for the Diploma in Psychological Medicine.

The claim is not good in law; the expense cannot rightly be said to be incurred wholly, exclusively and necessarily in the performance of the duties of the appointment, although they were incurred in connexion with the professional work. There is some parallel between such expenditure and the capital outlay incurred in getting together or improving the equipment of a general practitioner.

"C. S." inquires (1) what is the legal authority dealing with the right of deducting expenses from public salaries, and (2) whether pay earned as a locumtenent is "casual" and therefore not assessable?

(1) Schedule E, Rule 9 of the Income Tax Act, 1918, provides that expenses incurred wholly, exclusively, and necessarily in the performance of the duties of the office or employment can be deducted. There has, so far as we are aware, been no case before the courts dealing in this connexion with subscriptions to professional associations or payments for professional periodicals. (2) Tax is chargeable in respect of "every employment by retainer in any character whatever, whether such retainer shall be annual or for a longer or shorter period," etc., etc. Case 11, Schedule D, now transferred to Schedule E under the Finance Act, 1922. We are of opinion that "casual" earnings as a locumtenent are chargeable to tax.

## LETTERS, NOTES, ETC.

DR. C. E. BEGG (Bath) writes to state that the respiratory sounds can be well heard through a jacket of antiphlogistine spread a quarter of an inch thick on ganges tissue and applied direct to the skin. The fact is, he thinks, not well known.

### "WHAT ABOUT RIBS?"

IN one of his essays Mr. E. V. Lucas says that when he goes on a railway journey he makes a point of selecting from the bookstall periodicals which have nothing in common with the ordinary routine of his life, and in which he finds much amusement and refreshment. Among his favourites are the domestic journals published in the interests of music-hall artists. So, too, when the eye is perhaps a little fatigued by the serious medical journals of many nations, comic relief is found sometimes in such periodicals as *The Abolitionist* (an antivivisection organ) or *The Vaccination Inquirer*. To them must now be added another periodical, *The Journal of Osteopathy*, which though apparently not new, is new to us. Passing over the "professional cards" (among which one notes a specialist in "official surgery") and an advertisement of *Right Living*, "the aristocrat of osteopathic literature"—which has a cover that "looks like leather," and "will not be dated"—we are arrested by nine and a half pages of a "symposium" entitled "What about Ribs?" Osteopaths from far and wide have sent in their comments on some remarks made in a previous issue of their journal. O. A. Porter writes: "I wish I could be sure in the diagnosis and treatment of ribs. They surely exist, but I have seen very few where I felt reasonably sure of my diagnosis and less in which I was sure of correction." O. B. Gates writes: "I say ribs are very important and should be adjusted whenever out of line, which is very frequent indeed." Fred Taylor writes: "I am strong on ribs, and believe we overlook many rib lesions. I agree they are hard to reduce." S. B. Kiblinger writes: "Ribs cause lots of trouble, as do the vertebrae. I find many cases where the ribs are wholly at fault." G. C. Wilke writes: "Ribs are hard to adjust, and most of us don't adjust them either. All severe heart conditions, that I have found due to lesions, were due to rib lesions. A very important subject." E. C. Murphy writes: "I fix ribs." Ernest Fessenden writes: "Ribs are hard, especially when the one affected is over the heart, and patient thinks he is dying of heart trouble. Ribs, I find, must be fixed independently of the vertebrae. When you do fix this 'heart disease' your reputation is made." Harry Sinden writes: "Ribs are a cinch. But be sure the pelvis is straight before you attempt to correct any rib lesion." Edith W. Pollock writes: "Why can't any osteopath adjust rib lesions? I didn't know they couldn't. The ones who can't, would better go back for a P.G. course in technic or brush up on anatomy, and think." That, however, is the point. Are people who can write such arrant nonsense capable of thinking?

### HICCUP.

DR. H. J. FARNON (Reigate) writes: In the JOURNAL of January 13th I was interested in finding a reference to Mr. Money's remedy for hiccup—namely, drinking out of the opposite side of the glass. It so happened that a few months ago I had an attack of hiccup which lasted three days continuously. In desperation I tried this humorous remedy. Lying across the bed on my abdomen I bent my head downwards over the edge of the bed almost to floor and in this attitude I managed to perform the feat of drinking water from the far side of the tumbler. I have not hiccuped since. I consider that it is the attitude of head downwards rather than the cessation of breathing which is the effectual item of this cure.

LIEUT.-COLONEL G. T. LANGRIDGE, R.A.M.C., ret. (Bournemouth), writes: Over forty years ago my wife saw the method used by a young artillery officer, a guest at her father's house. He was attacked by hiccups at dinner, and drank out of his finger bowl in the manner described, and they ceased at once. It made an impression on her, and I have seen it often used by friends and have never known it to fail.

### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 37, 38, 39, 42, and 43 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 40 and 41.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 37.

## SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	0 9 0
Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Half single column	...	...	3 15 0
Half page	...	...	20 0 0
Whole page	...	...	20 0 0

Advertisements should be delivered, addressed to the Manager, 422, Strand, London, not later than the first post on Tuesday morning. If not paid for at the time, should be accompanied by a cheque.

NOTE.—It is against the rules of the Post Office to receive postage letters addressed either in initials or numbers.

## A Hunterian Lecture

ON

SOME PROBLEMS OF GASTRIC AND  
DUODENAL ULCER.DELIVERED BEFORE THE HUNTERIAN SOCIETY OF LONDON,  
JANUARY 20TH, 1923.

BY

SIR BERKELEY MOYNIHAN, Bt., K.C.M.G., C.B.,  
F.R.C.S.SENIOR SURGEON, LEEDS GENERAL INFIRMARY; PROFESSOR OF  
CLINICAL SURGERY, UNIVERSITY OF LEEDS.

A BACKWARD look over a few years in the course of a man's life may be of great value. It is very necessary for the surgeon, whose opinion and whose practice can rarely stay unchanged. For he is one who must always be in eager search of a sounder judgement, or a better method; reluctant to abandon any well proved conclusion or trusted procedure, he will yet remain quick to give the fullest consideration to all the lessons that increasing experience may seem to teach. To review our own work is a very stern and salutary discipline. It will make clear the need to correct the impressions, often vague and sometimes very treacherous, which have been gained rather than the occasional dramatic occurrence than from the tranquil observance of a daily and placid routine; it may confirm our faith in convictions which have slowly grown, and strengthened almost imperceptibly; it will lead us to test once again an opinion not quite so impregnable as we had thought. The correlation of many incidents, apparently unrelated at the scattered times of their occurrence, will provoke a new inquiry or reveal a truth which lay buried deep. From a long array of cases we can glean knowledge that the single case can never disclose. The years certainly teach much that the days never knew.

For the purpose of this address I have passed in review my experience during the last ten years in the treatment of diseases of the stomach and duodenum. The literature of this subject is already formidable in volume, but unhappily its value is by no means proportionate to its bulk. The foundations of physicians and surgeons are not wholly to blame. We have come into a deceptive inheritance; a large part of what we thought was gold has proved to be tinsel, the authority of a great name alone bestowing any interest upon it. Here at least we may agree with Damascenus, that "without exquisite knowledge, to work out of books is most dangerous."

In the older literature there is, however, much of great value. Matthew Baillie, Craveilhier, Brinton, and a very few others may be read with interest and profit to-day. After them came a host of authors nearly all of whom taught what has proved to be rank error in connexion both with gastric and duodenal ulcer. Gastric ulcer was held to be a common disease, diagnosed with ease if certain symptoms were present. Of duodenal ulcer almost nothing was known; its occurrence was held to be very rare, its diagnosis difficult or unattainable. In the literature of the hour a great deal has still to be taken on trust. And we shall never arrive at the truth about these diseases until we refuse to accept anything on trust—until we decide, for example, that when we speak of a case of "gastric ulcer" we really do know that an ulcer is present. Not all even of the surgical literature of to-day will stand that simple test.

A definition of terms is necessary. I hold that a "chronic ulcer," whether of the stomach or of the duodenum, is a visible and palpable lesion which has existed for months or years. In it are seen clearly the evidences not only of destruction but of stubborn defence; there is a crater of varying size; in depth the ulcer involves at least the muscular coat, and may extend completely through all the coats, an acute perforation being prevented only by the firm adhesion of the ulcer to a neighbouring structure, which then forms its base. Such an ulcer is the cause of symptoms the chief character in which is the tendency to show intervals of freedom between attacks of pain. The cause of the symptoms is not the ulcer alone, for in the intervals of freedom the inert crater of an ulcer is still to be seen; and open ulcers are found *post mortem* in those not known to be suffering immediately before death from any symptoms of dyspepsia. It seems possible that an ulcer in the perfectly callous state does not provoke any symptoms until the time when there is renewed activity in the ulcerative process at a

part of the circumference of the crater. Activity and apathy of the ulcer are in this way the cause of exacerbation and remission of the symptoms. Transient attacks may be due also to the development of a number of acute ulcers round about the chronic ulcer or in an area of the stomach apposed to it. The breaking down of a healed scar has been seen in a small number of cases. Acute infections elsewhere may rouse activity in a dormant ulcer. The term "acute ulcer" is used to describe a condition in which chaps, fissures, erosions, or extensive surface destructions of the mucosa, or even of deeper layers, are found. There is often clear evidence of an impediment to the vascular supply resulting in a defenceless area, of which the gastric juice makes haste to take advantage. The ulcers thus arising develop rapidly often as terminal events, in consequence of a very heavy infection or a grave toxæmia, and they probably heal very rapidly. Their clinical importance is generally apparent only when hæmorrhage or perforation occurs, though a profound dislike of food, severe epigastric pain and vomiting controlled with difficulty, are to be attributed, in cases of acute septic disease, to the gastric erosions which are found on *post-mortem* examination. Acute ulcers are multiple; it is possible that a chronic ulcer begins in one of the acute ulcers that refuses to heal. We do not know any clinical symptoms which indicate the transition from an acute to a chronic ulcer, assuming such a change to occur. It is the chronic ulcer in the stomach or in the duodenum which is the cause of severe, protracted, and recurring attacks. It is with chronic ulcer alone that the following remarks are concerned.

The number of cases here reviewed is 718. These were as follows:

- 531 cases of duodenal ulcer (men 433, women 98).
- 164 cases of gastric ulcer (men 83, women 81); in 152 cases one ulcer was present, in 12 cases two or more ulcers.
- 23 cases of gastric and duodenal ulcers together (men 10, women 13).

In the total number of cases of gastric ulcer (187) a duodenal ulcer was found therefore in 12.3 per cent.

The last death from any operation for duodenal ulcer occurred in 1912; there have been over 500 consecutive cases without a death. Among the total number of patients operated upon for duodenal ulcer there were 6 who later developed jejunal ulcers. The mortality in cases of gastric ulcer, and gastric and duodenal ulcer, treated by gastrectomy is 1.6 per cent. A few cases have been treated by other methods to be mentioned later. In every case included in this review an ulcer has been seen and demonstrated. It is an essential preliminary to call attention to this fact, for so much of what is written is based upon opinions as to what may be present rather than upon certain knowledge of what in truth is present.

There is creeping into the literature of this subject the term "juxtapyloric" as applied to ulcers. It is an entirely unnecessary term; its use indicates loose thinking and will lead to great confusion. An ulcer is either in the stomach or in the duodenum. In the series of cases which I am now reviewing there have been three only in which there was any doubt as to the exact position or origin of the ulcer. The pyloric vein or veins and the pyloric white line indicate with quite sufficient clearness the separation between the stomach and the duodenum. A duodenal ulcer is almost always half an inch or more from these landmarks, though it may extend up to them, or even beyond them into the stomach. A gastric ulcer is very rarely within an inch and a half of the pylorus; it is with the fewest exceptions two inches or more from the pylorus, and is oftenest found on the lesser curvature or the posterior surface or both. A pyloric ulcer, an ulcer beginning exactly at the pylorus, is excessively rare. "Pyloric stenosis" is virtually always duodenal stenosis. For the term "juxtapyloric" there is no justification; its use betrays a lack of knowledge of the conditions found when the parts are inspected during life; it is a peg upon which to hang the half-truths.

The chief clinical symptoms of ulcer of the stomach are pain, vomiting, and hæmatemesis, and of these the really important one is pain. The supremely significant feature with regard to the pain is its punctuality. In the same patient after the same meals it appears with the most exact regularity after the same interval of comfort. If a breakfast is taken at 9 a.m. and pain appears at 10 a.m. on one day, the same breakfast on all other days will be followed by the same hour of comfort and the same appearance of pain at the same moment. A time-table of one day, then, fits any other day.

Far less attention than it merits is given to a searching analysis of a day's routine. A patient will not seldom tell you he can "set his watch" by the time incidence of his suffering. The periodicity of the pain is, of course, altered by variations in the quantity and quality of the food and by the irregularity of meals. A point which is well worth attention concerns the rhythm of the pain. In cases of gastric ulcer the pain which, after an interval, follows the taking of a meal gradually disappears before the next meal. In cases of duodenal ulcer the pain continues until the next meal, or until food is taken to give ease to a wearisome pain. The rhythm of gastric ulcer is "food, comfort, pain, comfort," and then again food, comfort, pain, comfort; of duodenal ulcer it is "food, comfort, pain," and then again food, comfort, pain—a quadruple rhythm in the former disease, a triple rhythm in the latter. In my series of cases pain appeared within one and a half hours in 3 cases out of 5 of gastric ulcer, and after two hours in 4 cases out of 5 of duodenal ulcer. Seasonal variations are common in duodenal ulcer, less noticed in cases of gastric ulcer. The occurrence of haematemesis is often held to indicate with great probability the presence of a gastric ulcer. Haemorrhage in formidable quantity cannot occur apart from a considerable lesion of the stomach, oesophagus, or duodenum. In the stomach such a lesion may be a chronic ulcer or an "acute" ulcer. In years gone by, when operations were performed as mistaken efforts at resuscitation in cases of copious haematemesis, the mucous membrane was often seen to be studded with tiny points from which blood was steadily trickling—the stomach "wept blood." The blood came from multiple points of acute ulceration. If a patient has so large a haematemesis as to cause death, and if the cause of the bleeding is the erosion of a vessel in a gastric ulcer, a chronic ulcer will be found far more often than an acute ulcer. So many cases of haematemesis are due to the toxæmia of appendicitis or other grave infections, to cirrhosis of the liver, and to splenic anaemia, that no hasty conclusions as to the presence of a chronic gastric ulcer may be drawn from the occurrence of this symptom. In cases of duodenal ulcer both haematemesis and melaena may occur; the latter is almost invariably in excess of the former in quantity and frequency.

A very close scrutiny of all the details of the clinical history allows a diagnosis of duodenal ulcer to be made with a considerable degree of confidence. There should always be hesitancy in making a diagnosis of gastric ulcer. A duodenal ulcer is far more common than a gastric ulcer, and therefore when an "ulcer history" is elicited, a suggestion that the ulcer lies beyond the pylorus has the greater chance of accuracy, since probability is the very guide of life. But there is more to be considered than that. There are so many conditions having their origin elsewhere, within the abdomen or outside it, that are expressed in terms of gastric discomfort that even the most searching analysis of all symptoms may leave us unconvinced that a structural lesion in the stomach is present. I may perhaps sum up my experience of the clinical diagnosis of these two conditions by saying that when, with great confidence, I make the diagnosis of duodenal ulcer from the clinical history alone, I feel wounded and amazed if I prove wrong; whereas when, with a sense of pride in my courage, I make the diagnosis of gastric ulcer, I feel very contented, even a little elated, if I prove right. We turn, therefore, eagerly in all cases of gastric ulcer to other methods of examination in the hope of greater enlightenment.

Of all ancillary methods of diagnosis that of the radiologist should be of greatest value. In the diagnosis of gastric ulcer it has pride of place; in competent hands it is far more accurate than any other method of diagnosis, clinical or chemical, or than all other methods combined. It is, indeed, so trustworthy that unless a diagnosis of gastric ulcer made upon clinical evidence is confirmed by the radiologist it should rarely, if ever, be accepted. There are, indeed, only two certain and unequivocal methods of making a diagnosis of gastric ulcer—that of the radiologist and that of the surgeon. Unless a gastric ulcer is seen we can never be quite confident of its presence. We must walk by sight and not by faith. I think it is quite true to say that no merely clinical diagnosis of any condition is so apt to be fallacious as is that of "gastric ulcer." Yet cases are met with very frequently in which this diagnosis has been made upon the flimsiest clinical evidence. When such a diagnosis becomes the warrant for medical treatment, when such treatment is expanded into a "system," and when the statistical results of such systems

are offered for our consideration and respectful admiration, we cannot but feel aghast at the mountain of falsity which looks so imposing and is in truth so unreal. Until we have learnt far more than we know at present, might we not resolve to apply the term "gastric ulcer" only to the cases in which the diagnosis is certain, and to judge of the efficacy of therapeutic methods, and of the pathological destiny of the lesion, only in such proven cases?

The radiological evidences of an ulcer have been fully described by Carman and others. The niche or accessory pocket has been well seen in exactly one-third of our cases; the abiding spasm of a zone of the stomach, the "notch" on the greater curvature, seen with or without the crater, indicates just as certainly as the niche the presence of an ulcer. The condition of the stomach in respect of its general muscular tone is now always observed; it is interesting to find that the orthotonic, the hypotonic, and the hypertonic types occur with exactly equal frequency in cases in which a gastric ulcer has been proved to exist. In cases of duodenal ulcer an orthotonic condition was found in 44 per cent., a hypotonic in 24 per cent., a hypertonic in 32 per cent. Deformities of the duodenal bulb are as certain an evidence of ulcer as are the niche and notch in cases of gastric ulcer. When stenosis has resulted from the firm healing of an ulcer, whether in the stomach or duodenum or both, the radiological examination reveals the clearest proof of the conditions present.

An additional method of inquiry which we follow in the great majority of cases consists in the examination of the gastric contents by the fractional method of Rehfuess. In my earlier experience I had several hundreds of cases examined after an Ewald test meal, but I found that so little helpful information was given at so great an expense of time and trouble, both to the patient and to ourselves, that I was glad to abandon the procedure altogether. The new method, which we have used for over a year, is more rational and has been most informative. The following table shows the results obtained, the classification of the six grades of acidity being that suggested by Dr. J. R. Bell of Melbourne, to whom I am indebted for a part of this work.

Results of New Method of Examination of 110 Cases of Ulcer.

	Gastric Ulcer (39 Cases).		Duodenal Ulcer (71 Cases).	
	No. of Cases.	Per Cent.	No. of Cases.	Per Cent.
Achlorhydria ... ..	5	13.1	4	5.5
Hydrochlorhydria ... ..	6	15.7	3	4.1
Low normal ... ..	7	18.4	9	12.8
Normal ... ..	13	34.2	4	5.5
High normal ... ..	6	15.7	17	24.2
Hyperchlorhydria ... ..	2	5.2	34	48.5
Curve with terminal ascent	1	0.2	21 (in 45)	46.6
Stomach empties—				
Within 2 hours ... ..	7	18.6	20	28.5
Between 2 and 3 hours ...	12	31.5	35	50.0
Over 3 hours ... ..	18	47.3	16	22.8

It will be noticed that only 20 per cent. of the cases of gastric ulcer show a high normal curve or hyperchlorhydria, whereas the percentage of such changes in cases of duodenal ulcer is 72.7. The most characteristic feature of the chart ulcer is 72.7. The most characteristic feature of the chart ulcer is the "terminal ascent," yet this was present in less than half the cases. Delay in emptying the stomach was conspicuous in both groups. The rapid emptying of a hypertonic stomach when the test meal showed hyperacidity or a high normal curve was found in 6 cases of duodenal ulcer, and in one case where there was a small gastric ulcer high on the lesser curvature.

To compare with this table I show another compiled from the records of patients referred to me as probably suffering from gastric or duodenal ulcers. In none was any ulcer discovered, in 2 cases a hypertonic stomach emptied rapidly and the Rehfuess chart indicated hyperchlorhydria, in one a similar gastric condition was associated with a low normal type of acidity.

23 Cases of Chronic Infection within the Abdomen, including Cases of Appendicitis, Tuberculous Disease of Intestine or of the Mesenteric Glands, all Clinically Resembling Gastric or Duodenal Ulcer.

	Cases.	Per Cent.
Achlorhydria ... ..	3	13
Hypochlorhydria ... ..	8	34.7
Low normal ... ..	5	21.7
Normal ... ..	6	26
High normal ... ..	7	4.3
Hyperchlorhydria ... ..	1	4.3
Curve with terminal ascent ... ..	3	13
Stomach empties—		
Within 2 hours ... ..	4	17
Between 2 and 3 hours ... ..	12	52
Over 3 hours ... ..	7	31

Let us assume that a diagnosis of gastric or duodenal ulcer has been made with great confidence. The question will at once arise as to the method of treatment that has now to be adopted in order to relieve the patient of his symptoms, and finally to remove the grave peril to his life which the disease undoubtedly threatens. There has been great strife between physician and surgeon over this matter—strife in which I must confess to the most languid interest. I claim that I rarely offer advice to patients. My endeavour is to present a case for consideration, to discuss the probabilities of diagnosis and the reasons for and against any method of treatment, whether medical or surgical. Being a physician doomed to the practice of surgery, I feel no desire to press one method or another, and I most earnestly seek to put the whole problem before the patient as I should put it before myself or before anyone near and dear to me. I ask a patient to assume—what may prove to be inaccurate in the case now for discussion and decision—that my diagnosis is right, and that he has an ulcer in the stomach or in the duodenum. The relative advantages of medical or surgical treatment are then to be considered.

In all the cases that come for judgement symptoms have been present for years. During the last ten years the average duration of symptoms has been seven and a half years in cases of duodenal ulcer (excluding the perforation cases, when the duration is shorter), and nine and a half years in cases of gastric ulcer. Every patient has been treated by a medical man in one or in many of his "attacks"; medical treatment has helped greatly to relieve the pain and to curtail the attacks, but a period of repose has been followed at greater or less length by one of renewed and perhaps fiercer activity. Medical treatment, then, has failed in its essential aim, the permanent healing of the ulcer. And there is some reason to fear that it will inevitably fail in a majority of the cases. Anyone who knows the appearance which a chronic ulcer of the stomach or the duodenum presents at the time of operation will realize how considerable an event it must be for sound healing to take place, and how prone the large and deep scar which so results may be to break down under a provocation that the normal stomach would perhaps easily resist. That healing does sometimes take place is shown by the discovery of sound firm scars in the *post-mortem* room. It is evident that to ensure complete cicatrization of the ulcer the greatest care must be exercised from the first, and be scrupulously and unremittingly continued over a prolonged period.

The medical treatment of these conditions is too often haphazard and perfunctory. So far as hospital patients are concerned I think it is hardly possible to ensure that they shall receive adequate treatment over a sufficiently long period. No hospital can afford to keep them as in-patients, and as out-patients they prove careless, and are unable to observe, or wilfully disregard, the instructions as to rest and diet that are given to them. In private practice few patients seem willing to surrender themselves whole-heartedly to treatment, and especially to what appears to be a wearisome prolixity of supervision long after symptoms have completely disappeared. I should suppose that a great many weeks in all cases, and perhaps many months in some cases, must be passed in bed, on a restricted diet, appropriate drugs being duly administered, before an ulcer with a large surface, a deeply excavated crater, and a hard unyielding edge, can have any chance to heal.

It is important to remember that the subsidence of symptoms often noticed very shortly after treatment has begun does not indicate the healing of the ulcer; for every surgeon knows, as I have said, that in operating after an "attack" has subsided, an open ulcer crater may be found. Treatment must therefore continue long after all pain has disappeared. In the operation I sometimes practise for irremovable gastric

ulcer—that is, gastro-enterostomy combined with jejunostomy—the patient is fed through a tube which passes directly into the jejunum, and no smallest quantity of food, solid or liquid, is given by the mouth. The healing of the ulcer is watched by screen examination with the x rays. It is always very slow—it has varied from six months to three and three-quarter years. A longer period, we must suppose, will be demanded if food even of the blandest kind is taken by the mouth, for the contact of food with the raw surface of the ulcer, the retention of particles of food in recesses of the crater, and the active movements of the stomach, especially if the ulcer is adherent, are all incidents likely to retard the deliberate processes of healing.

Before treatment begins a general survey of the patient must be made, especially in reference to the existence of sources of infection in the mouth and the accessory sinuses. I never operate upon a case of gastric or duodenal disease until the dental department is satisfied that there is no infection remaining in the mouth; a great deal may require to be done before this result is assured, but whether we regard the risk of the anaesthetic or the diet after operation, it is a most essential preliminary.

Most of the "systems" of medical treatment have as a very essential part the administration of alkalis. The "Sippy" method includes the frequent administration of alkalis by the mouth, and the practice has been carried to an extreme which in a very few instances appears to have been harmful. It is interesting to note that in nearly 50 per cent. of our proved cases of gastric ulcer the Rehfuß chart has shown a subnormal curve, in nearly 35 per cent. a normal curve; in only 5 per cent. was hyperchlorhydria present. Has the practice of the administration of alkalis originated in a desire to neutralize the "acidity" of which the patient sometimes complains, although it may chance that he has an amount of free hydrochloric acid less than the normal? Or is it based upon the chemical examination of the stomach contents of patients who are only said to have "gastric ulcer," and not certainly known to have one? The great discrepancy which exists between the alleged frequency of gastric ulcer in practice and the known rarity of the disease upon the operation table is a reason for accepting the diagnosis with most cautious hesitation in large numbers of cases. If that hesitation is justified, much of the medical treatment of "gastric ulcer" is being applied to quite different diseases. I would like to ask whether an "acid" treatment of gastric ulcer would not be more rational than an "alkaline" treatment. The cells of the gastric mucosa are born, live, thrive, and, in due course, perish in an acid medium. In cases where a gastric ulcer has been proved to exist a diminished acidity is far more common than an increased acidity. If the result of the administration of the alkali is to provoke a later acid response (this is certainly true of sodium carbonate in particular) then the treatment is rational; but this, I understand, is not the ground upon which the alkaline method is based. And I would further ask why the medical treatment, including the giving of alkalis, is the same in cases of duodenal ulcer as in cases of gastric ulcer. The chemical conditions in the two diseases are quite dissimilar.

#### VALUE OF MEDICAL TREATMENT.

The position with regard to the value of medical treatment appears, then, to be as follows:

##### I.

Medical treatment, scrupulously undertaken, will almost invariably and with great rapidity cause an alteration in the gravity of the symptoms; the patient will quickly lose the severe pain from which he has suffered, and will begin to wish for, and find himself freely able to take, those simple foods which are most easily digested and easily propelled. The "attack" may be brought to an end within a very few days in the case of duodenal ulcer, and within two or three weeks even in the case of those most recalcitrant gastric ulcers which have intermittently caused symptoms for many years. So far as I have been able to tell from an examination of the specimens removed by operation symptoms disappear as soon as an ulcer shows any evidence of healing; the ulcer, though still large and unhealed, becomes "latent."

Medical treatment must, however, necessarily be carried out, not only in ignorance of the exact conditions present in any ulcer, for not even the most expert radiologist can tell us all that we are eager to know, but also in ignorance of the associated and possibly causal infections present within the

abdomen. In this series of 718 cases I have removed the appendix 307 times, and the gall bladder 23 times. In more than 50 cases the gall bladder, or the appendix; or both, had been previously dealt with by operation. In many of the cases in which I have removed the appendix I have felt that its obvious and sometimes gross disease antedated the development of the ulcer or ulcers in the stomach or duodenum, and I have consequently regarded it as a primary source of infection. An occasional case has seemed to give support to the view of Arbuthnot Lane, that the colon plays a part in the causation of gastric disease; and in a few cases the very loose and overfull ascending colon has tempted me to follow the practice of Waugh and to fix this part of the bowel by his method to the posterior abdominal wall.

The interrelationship of abdominal disease is, as yet, rather a matter of confident surmise than of certainty. The tenacity with which some surgeons hold their extreme views upon this subject often seems in little proportion to the evidence they adduce in support of them. Convictions masquerade as truths. The strength of a man's conviction may display only the defect or weakness of his knowledge. Our acquaintance with the so frequent associated disease in the appendix, with the mimicry of the symptoms of ulcer by a diseased appendix, with the "pyloric blush" which is caused by a lymphangitis spreading to the stomach from other parts, with Wilkie's work on retrograde embolism in the cecum, with Braithwaite's on the lymph drainage of the ileo-colic angle, and so on, leads to a realization of the truth that medical treatment can do nothing to inform us upon many of the relevant matters which it is most desirable, indeed essential, that we should know. If it is necessary to clear away oral sepsis before commencing medical treatment, it cannot surely be a matter of negligible importance to allow the persistence of any infective lesion within the abdomen; for this, too, may be a primary or at least a contributory causal agent. It is therefore as a method of temporary solace, of postponement of discomforts or of impending dangers, rather than as a means for our enlightenment or for the cure of the patient, that medical treatment claims our appreciation, and on these restricted grounds it most warmly merits all that we can find to say in its favour.

## II.

Medical treatment, however loyally followed during an "attack" and for weeks or months after the symptoms have passed away, seems quite powerless to prevent recurrence of symptoms in a very large number of cases. So far as the patients who come to hospital are concerned the constant feature in their clinical history is the presence of "attacks" followed by periods of remission. In my present series there must be not less than one hundred patients who have submitted to a series of "treatments" involving rest in bed from four to six weeks on more than two occasions; there is not one who has not had medical treatment on several occasions, and, weary and disheartened, many of them turned only at a late hour to a surgeon for relief. A very distinguished surgeon has said that he rarely operates upon a patient whose ulcer has not been "cured" nine times. The cure which follows such treatment may last from a few months to a few years. There must be cases in which a recurrence never takes place, but although I have made a long search which cannot be called desultory among many patients, I have not met with half a dozen of whom this can truthfully be said. And the discovery of the scar of a chronic ulcer in the stomach or duodenum of a patient during the performance of an operation for disease elsewhere in the abdomen is excessively rare, as all surgeons know.

In the "recurrent attacks" the catastrophes which we dread so much may make their sudden appearance. If haemorrhage occurs we may be gravely perplexed as to what it is best to do. If we adopt medical treatment, rest in bed, abstinence from food, administration of an alien serum, intravenous injection of calcium chloride, or the direct transfusion of blood, the haemorrhage may be arrested and the patient recover sufficiently to brave the risks of operation. But in spite of all that can be done, or indeed before there is a chance to do anything, the patient may die. Last year I was consulted by three patients suffering from duodenal ulcer, all of whom had undergone prolonged medical treatment. Because of family or weighty business reasons they all desired to postpone operation. If I am asked in such cases to sanction delay I protest that I am a surgeon, not a prophet, and that I cannot foretell the risks that lie ahead and may be imminent. The three patients died of haemorrhage before

any surgeon had the chance to help them. If I am to find three patients who have died under my care after operation I have to go back many years and search nearly a thousand records.

With the help of Professor M. J. Stewart I have obtained a record of the cases of gastric and duodenal ulcer which have died in the Leeds Infirmary in the years 1910 to 1921 inclusive. Of gastric ulcers there were 75 in which death was due to haemorrhage or perforation and peritonitis. These grave catastrophes may occur in connexion either with "acute" or with "chronic" gastric ulcers. There were 61 deaths from perforation—in 60 cases the ulcer was of the chronic type, in one it was acute. There were 14 deaths from haemorrhage—in 13 cases the ulcer was of the chronic type, in one it was acute, and was a terminal condition in a case of advanced cardiac disease; the haemorrhage was not the only or chief cause of death. Deaths from these emergencies occur, therefore, comparatively rarely in cases of "acute" ulcers. It is the chronic ulcer in an acute phase that at last bleeds or perforates, and causes death. The patients with this type of ulcer have, almost without exception, undergone treatment not once or twice only, but many times. It is true that the treatment has often been brief, and that it has ceased rather in consequence of a patient's negligence than because the medical attendant had sanctioned its omission. The warning to every patient that the checking of the symptoms does not mean closure of the ulcer is very necessary.

During the same period there have been 129 cases in which death was directly attributable to haemorrhage from a duodenal ulcer or from perforation. There were 12 deaths from haemorrhage; in all the ulcer was of the chronic variety. There were 117 deaths from perforation. In 12 of these there was an acute ulcer; in 4 of the 12 chronic ulcers also were present, and in each case it was the chronic ulcer which had perforated, the acute ulcer being merely incidental. In the remaining 105 cases the ulcer or ulcers were of the chronic type. Perforation, therefore, is found here also far more commonly in cases of chronic ulcer. A full clinical history is not always to be obtained, for even nowadays patients are brought in a moribund state to the hospital two, three, or four days after the catastrophe has occurred. But the records show that the very great majority of patients had undergone treatment, for longer or shorter periods, on a number of occasions. The full mortality of surgery is known, but all is not yet disclosed of the death rate among patients "cured" of their attacks who die months, or it may be years, later in the acute emergencies from which there is no time to rescue them.

## III.

In cases of gastric ulcers treated medically we cannot afford to neglect a consideration of the problem of carcinomatous degeneration at the edge of a simple ulcer. Opinions upon this matter appear to be irreconcilable, in consequence, I believe, of different aspects of the total volume of evidence being alone considered by each of the contending parties. I can only speak of cases that I see, and these are, of course, largely, but by no means exclusively, a very special group in which all efforts other than those a surgeon can make have been exhausted. I operate upon rather less than half the cases sent for operation, so that I may lay claim to some knowledge of cases that are labelled "medical."

Of the cases of cancer of the stomach that I see upon the operation table a steady average of two out of three give a past history that is extremely suggestive of gastric ulcer. That such a history is apt to prove fallacious or misleading no one knows better than I do, but before I admit the history as probably indicative of ulcer I sift it very carefully and discount it as much as possible. In some such cases an ulcer, apparently of the usual chronic type, may be entered the time of operation. No slightest suspicion may be entertained as to its malignancy from any naked-eye examination that is made. Under the microscope early malignant changes at one edge only of the ulcer are found. This has been the case in 18.5 per cent. of the supposed chronic ulcers. In other cases a chronic simple ulcer is seen, one edge of which is thickened, upraised, red, and softer than the normal rigid, steep or overhanging edge. This part shows carcinomatous changes. In one case there were two such patches at opposite edges; one showed columnar carcinoma, the other scirrhous. Again, there are cases of duodenal ulcer where the symptoms are often unequivocal and persistent, on and off, for years, in which a new and more formidable menace has lately appeared. At the operation a very old duodenal ulcer is seen

to have lately transgressed the line of the pylorus, and the gastric edge of the ulcer is found to be malignant.

In a long series of cases of gastric ulcer treated by gastrectomy, in which the pathologist has reported an absence of malignant disease, two patients have died of "recurrent" cancer with growth in the stomach or its glands, and the liver. Ulcers of the stomach, we are told, which exceed a certain size, roughly 1 inch in diameter, are always malignant. Does this mean that a simple ulcer never grows so large, or that a simple ulcer of such a duration as to grow to such a size inevitably degenerates to malignancy? When resection of the stomach is performed for frank carcinoma of the stomach, plain for anyone to recognize, the disease will probably have invaded a large part of the stomach. Every trace of an original chronic ulcer, if such there were, will then be overlaid by growth and be quite unrecognizable. If patients die of carcinoma of the stomach without operation the disease will be so advanced that there is little chance to discover any evidence of earlier disease. On the question of the incidence of cancer in ulcer *post-mortem* evidence is therefore of the slenderest value. It is in the examination of specimens of gastrectomy performed in the early stages of carcinoma that the only trustworthy evidence can be obtained. Is there any surgeon who finds that cases of this type are sent to him too early?

I do not profess to give any figures, but the cumulative effect of the evidence I have offered makes me acutely anxious as to the destiny of any patient suffering from gastric ulcer. If we regard the change from a simple disease to a malignant one as possible, even if infrequent, the method of gastrectomy in cases of chronic gastric ulcer clearly has advantages which no other operation can claim. Its mortality is much less than the mortality from that form of cancer of the stomach which proves fatal after gastro-enterostomy alone has been done for the supposed simple chronic ulcer in which the cancer has already started to grow, or in which it grows later when the ulcer refuses to heal. It is perhaps worth while to recall the fact that the real chronic ulcer is a rare disease. If gastric ulcer is considered a common disease—if, that is, the clinical diagnosis alone is accepted—the proportional incidence of carcinoma among such cases is certain to be very small.

#### IV.

Finally, the question may be asked whether, in the case of a gastric ulcer, medical treatment does in truth often attain its paramount object, the permanent healing of the ulcer. The answer is not so simple as it may seem. Before we can give that answer we must know, of any case—first, that an ulcer has without doubt been present, and the evidence of this must not be merely clinical; secondly, whether a radiological examination which confirmed the diagnosis now shows that the ulcer is healed; and thirdly, that the healed ulcer has not broken down again some months, or years, later. Is this evidence forthcoming even in a small number of cases? Of the supposed healing of a fictitious ulcer we have abundant evidence; but of testimony that fulfils the essential conditions I have mentioned there is almost none. Yet I most respectfully submit that if it is claimed that medical treatment can lead to the healing of an ulcer in the stomach nothing less than this degree of proof ought to be offered for our consideration.

The dangers of medical treatment, therefore, are very formidable. The mortality is far greater than with surgical treatment. It is probable that only the most serious cases are submitted to operation, yet the number of deaths occurring after operation is quite insignificant compared with the number of those who die without the chance of benefit by surgery. The deaths which occur unhappily with such great frequency from hæmorrhage or from perforation, whether patients are operated upon as the twelfth hour is almost striking or not, are deaths which have not been prevented by the medical treatment, which almost all the patients have had intermittently for months or years. A patient is just as dead if he dies after medical treatment as he is when he dies after surgical treatment. If he dies after an operation surgery will probably get the blame, and may occasionally deserve it. If a patient suffering from a gastric or a duodenal ulcer is treated medically on one or numberless occasions and dies from hæmorrhage or from perforation, such treatment must take the blame for its failure to prevent a fatal termination. The mortality is the mortality of medical treatment just as certainly as the mortality following an operation is the mortality of surgical treatment.

If, therefore, the physician claims these cases as "medical"

rather than "surgical," it is his plain duty to recognize that, whether we regard the risk to life, or the continual return of suffering, medical treatment is at present a far less effective and definitely more dangerous undertaking than any operation which the surgeon may practise. I say this not to encourage the physicians quickly to relinquish these cases to the surgeon, but rather to suggest that medical treatment should be raised to a general level of efficiency and of safety corresponding to that which surgical treatment has now reached. The occasional discovery of the scars of chronic ulcers of the stomach or duodenum in the *post-mortem* room makes it probable that even the most obdurate ulcers can sometimes be induced to heal, and perhaps to remain long healed.

#### SURGICAL TREATMENT.

The operative treatment of chronic gastric ulcers has passed through many phases, and there appears to be little chance of general agreement upon this matter even at the present time. The operation first to be practised was gastro-enterostomy, and in a very large number of cases the results have been good. But to satisfy the demands which the surgery of to-day must be fully able to meet, the results have not been good enough. A reference to the table of gastric analysis will show that in rather more than half the total number of cases there is a little delay in the emptying of the stomach. It is now well known that an ulcer on the lesser curvature of the stomach, far away from the pylorus, may be associated with so considerable a degree of spasm at the pylorus that the gastric contents are unable to escape at the normal rate. In such cases gastro-enterostomy will permit of easier drainage of the stomach, and according to its advocates will "give rest" to the ulcer. The objections to gastro-enterostomy, however, outweigh all its trivial advantages. The simplicity of the operation is one of its greatest dangers; for the operation is practised far too frequently by inexpert surgeons. It is performed when no ulcer is present, the lesion primarily responsible for the gastric symptoms being overlooked; it is performed in place of more appropriate operations, and is followed perhaps by temporary relief, when they would result in "cure"; its performance, in the hands of some of its warmest advocates, has a mortality as high as that of more radical operations, and is followed in too large numbers by the development of cancer in the ulcer which the operation fails to remove. The operation is believed to have a "physiological" effect, and this is supposed to have a beneficent influence upon the healing of the ulcer; no adequate evidence has ever been offered that tempts me to indulge my credulity so far as to accept either of these fictions. Gastro-enterostomy acts mechanically and in no other way.

The operation has been combined with excision of the ulcer, or, as by Balfour, with destruction of the ulcer by cautery. Clean excision of the ulcer by the knife appeared to be a method full of promise. I practised it many times, and discarded it in consequence of the large proportion of cases in which the ulcer recurred. Balfour's operation has the great advantages that it destroys the ulcer completely, and that it destroys also, because of the selective action of heat upon the cancer cells, any early malignant degeneration that may have set in at the margin of the ulcer. Balfour, whose opinion always carries great weight, has pleaded for this operation with eloquent cogency (*Annals of Surgery*, 1921, lxxiv, 448), and all those who practise it at the Mayo Clinic are well satisfied with it. I practise it very rarely, reserving it exclusively for ulcers of small size high up on the lesser curvature, associated with pyloric spasm and gastric retention. Ulcers in this position are sometimes most inaccessible, and are apt to form adhesions to the pancreas or any near structure. The removal of them by gastrectomy would mean that the whole stomach would be sacrificed—a grave measure out of all proportion to the needs of the case. I therefore in such instances choose either Balfour's operation, or more often and by preference the method of gastro-enterostomy in Y combined with jejunostomy. This latter method has been most valuable in cases of extensive indurated inaccessible ulcers, firmly grown to the diaphragm or liver or pancreas. In such cases, especially if hæmorrhage has occurred, or if there is a profound degree of inanition, a resection of the stomach would be sometimes impracticable, and always a most formidable or highly dangerous procedure. The complete rest to the stomach which the operation of jejunostomy affords gives fullest opportunities to the ulcer to heal. An examination by the radiologist from time to time will show that, unhappily, the

In a case of insomnia our procedure may be simple enough, but it may, on the other hand, involve much patience and the exercise of considerable self-confidence and analytical powers of no mean degree.

In the light of present-day knowledge we may assume that the area of conflict and unrest is in the cerebral nerve centres. When these centres are unstable through inherited defects we must regard the case as capable of only partial relief, whether our remedies be psychological, physical, or chemical. We may discover that a hypersensitive condition of the cortex has been brought about by fatigue, arterio-sclerosis, excessive or diminished blood pressure, toxins or excitants of various kinds—alcohol, tea, coffee, etc. Here, of course, we try to remove the causes. In high blood pressure a hot foot-bath, or a whole body bath with or without mustard dissolved in it, gives considerable relief; mustard packs to the lower limbs and abdomen may draw the blood from the brain and give a good night's sleep; massage with brushing of the body is also of use. In these cases of high blood pressure the condition of the bowel must be carefully watched and constipation prevented. Suitable intestinal antiseptics may be indicated. Where the brain unrest is due to psychic disturbances, such as a sense of loss, material or spiritual, fear, rage, hate, the treatment will depend on the severity of the case and its duration. Generally, a change of air and scene should be recommended before drugs are given.

A stage is reached in a large number of cases of insomnia such as the foregoing in which no external treatment, no change of surroundings, will avail, and we find the patient going from bad to worse, often rapidly. It is in such a case that the psychotherapist is seen at his best. If he is a student of comparative religions he may bring solace to the Roman Catholic by encouraging him to repeat certain formulas, by counting beads, and indulging in religious exercises that have a strange but potent sedative action. Patients of the reformed faith may find happiness in contemplating the promises of the gospels, the fatherhood of God, and the brotherhood of man. Others, with or without the religious sense, may find escape from the brain storms by reading books that amused or edified them in the happy days of their youth—a revisiting, as it were, of old intellectual pastures associated with the pleasantest period of life.

It is always wise to reassure such cases. Many are really drifting towards the borderland of insanity, and we must try to arrest in them all sense of fear and despondency. In some cases we advise them to sit up late, play patience, or picture puzzles. Here is a remedy I have found useful: Get the patient to switch on the light and carefully write down on a piece of paper the ideas disturbing him. This often succeeds in breaking up a disturbing train of thought. Auto-suggestion in some cases is invaluable, and hypnosis often breaks the vice if it be not too long established.

Maccenas had a physician, Musa, who, as a remedy for the terrible insomnia of his patient, recommended him to live in a villa close to a cascade. The monotony of the waterfall was the only remedy that enabled the care-worn statesman to get some sleep. Our own Wordsworth had much the same experience.

Most people suffer from insomnia psychic in origin, at some time of life, and, as every man can best sit on his own hat, so most people have a way of their own for dodging unpleasant ideas, and what helps one person may not help another.

We have all, I dare say, met cases of psychic origin where, despite every artifice, the demon of insomnia had the best of it. Then comes the time for judicious drugging and external treatment. For the pressing need of sleep I have found that an hour's gentle massage at bedtime, immediately preceded by 3 grains of veronal and at the end of the massage period 10 grains of aspirin in hot milk, gives good results. Massage sometimes irritates, and when this is so must not be continued. Reading by a nurse is sometimes a fair substitute, provided her voice is soft and manner of reading monotonous.

In cases of weak heart 25 grains of chloralamid in an ounce of brandy may be given instead of the veronal, repeating the dose in three hours if necessary. With all its drawbacks I have found paraldehyde in 2-drachm doses with yolk of egg very effective in bad cases. Others doubtless have found other drugs quite as good.

When the insomnia is due to cerebral unrest originating at a distance from the cortex and with the impulses conveyed thereto by the nerves of sensation or those of the special senses the remedies are obvious. We remove when possible the causes of pain, the sources of cold, heat, sounds, and so on; and of course in actual painful conditions, in cases not

complicated with renal or bronchial defects, opium will suggest itself.

A case of insomnia that impressed me greatly was one due to neuralgia of the extremities. Luminal in 5-grain doses was the only drug that not only relieved the pain but gave several hours of refreshing sleep. The drug can be given dissolved in hot water or in a cachet. It is best to begin with doses of 2 to 3 grains and repeat three or four hours later in the night if necessary. Cases of insomnia due to pain require careful watching. Many such patients in time lose the sense of pain measurement, and undoubtedly exaggerate the degree of pain felt in order to get stronger and stronger remedies. It is an unsafe policy to leave drugs likely to poison within the reach of such patients.

For some time I have been interested in Professor Langley's researches into the sympathetic nervous system, now known amongst physiologists as the vegetative nervous system. An authority on the subject tells me that he believes that during sleep afferent impulses proceed towards the central nervous system along the vegetative nerve paths, just as they do during wakefulness. We are hardly guilty of forcing our imagination if we assume that herein may be found a new field for inquiry. I submit as a hypothesis that may explain a certain type of cerebral unrest not otherwise accounted for, that, unperceived by the individual, certain impulses from the thoracic, abdominal, or pelvic vegetative nervous system do reach the brain cells and upset the physiological processes there that otherwise would make for repose and sleep. One is more confirmed in this point of view by remembering how sleep may be brought about by remedies directed to relieve certain thoracic, abdominal, and pelvic conditions in which no actual pain is felt—for example, certain types of heart affections, indigestion, gastric and intestinal in origin, and pelvic irregularities, and so on. Anyone who has studied the calming effects on the central nervous system brought about by correcting the functional diseases indicated must be driven to the conclusion that here we may sometimes find the real cause of disturbed sleep. The phenomenon of nightmare must not be lost sight of in the light of this theory.

It is well to bear in mind that where the disturbance is not due to the nerves of common or special sensation we may find the vegetative nervous system at fault, and if so our prognosis is good. In quinine hydrobromide Dr. Langdon Brown believes we have a drug with specifically sedative action on the sympathetic nervous system.

In the foregoing remarks I have tried to pigeon-hole, as it were, the causes that give rise to sleeplessness. The nerve cells, then, may be disturbed by psychic forces within them, by forces chemical and physical around and penetrating them, by disturbing forces that sweep along the afferent nerves of general and special sensation, as well as those silent and unperceived impulses that proceed along the sympathetic nerve paths. The cell having been disturbed, sleeplessness ensues.

I think a close analysis of the causes of sleeplessness will help us to make fewer mistakes in treating the condition, and at any rate it is worth while to aim at isolating as far as we possibly can the chief factor at work in any given case. Often acting alongside this chief factor may be found other subsidiary and less aggressive influences at work. The latter we must deal with in turn; but the wolf nearest to our patient's heels is the most dangerous, and we will do wisely to destroy him first.

## INSTRUMENTS LEFT IN THE PERITONEAL CAVITY:

### AN ANALYSIS OF 44 UNPUBLISHED CASES.

BY

CLIFFORD WHITE, F.R.C.S.,

SURGEON, SAMARITAN HOSPITAL FOR WOMEN; GYNAECOLOGIST,  
METROPOLITAN HOSPITAL.

My interest in cases in which solid objects have been unintentionally left in the peritoneal cavity was aroused by having on two occasions to operate for their removal; perhaps I may mention that in both cases the foreign body had been left in the abdomen by someone else. The notes of the two cases mentioned are as follows:

## CASE I.

A patient, aged 50, was sent to me because her doctor had found a sharp foreign body in the canal of the cervix. She had consulted

him on account of constant pelvic pain. The history given was that nineteen years before she had had a laparotomy performed, in the country, for a "tumour," but no details could be obtained. Seven years after this she was delivered of a full-time child without difficulty, and had had moderate health except for one attack of severe abdominal and pelvic pain, which subsided under treatment with hot fomentations. The abdominal pain, with nausea and vomiting, gradually increased in severity for several years, and for these symptoms she had a second operation performed in hospital in the country, eighteen months before I saw her. She was informed that the adhesions in the lower abdomen were so dense that nothing could be done, and therefore the operation was abandoned and the abdomen closed. The pain and sickness increased, and six months later an offensive vaginal discharge commenced. There was frequent desire to defaecate, and frequency of micturition.

When I first saw her she looked toxicæmic and wasted. The abdomen was distended, and there was a tender mass below and to the left of the umbilicus. A hernia of the old laparotomy scar was present. On vaginal examination a pointed metallic instrument could be felt protruding through the cervix for 4 cm. from the external os. The body of the uterus was bulky, and situated in the middle line. There was a mass on the left of and above the uterus, continuous with the tender area on the abdominal wall. An x-ray photograph showed a Spencer Wells hæmostatic forceps, with the handles towards the left iliac fossa and the points in the cavity of the pelvis.

It was obvious that any attempt to remove it by traction on the pointed end would lacerate the uterus severely, and possibly also damage the ureters. I therefore opened the abdomen, and was faced by a mass of very dense adhesions. The forceps was found above the level of the bladder reflection: the points had penetrated the wall of the pelvic colon, and were lying inside the lumen of the gut. The forceps was removed and a panhysterectomy performed, in order to get rid of the infected uterus and to give free drainage to the faecal abscess that the forceps was lying in. Owing to the large deficiency in the gut wall, and the infiltration of the surrounding tissues, it was difficult to suture the hole in the colon, but finally the edges were united, and it was not thought necessary to do a colotomy. Large drainage tubes were inserted through the vagina and through the abdominal incision.

The patient stood the operation well, but a faecal fistula formed at the end of a week and was still discharging six weeks later. She then commenced to have peculiar attacks of collapse with cyanosis, loss of consciousness, and vomiting. The first attack came on after eating eggs which had been sent to the hospital, and she stated that she had never been able to eat eggs, as they had previously affected her in a similar manner. It was suggested that the attacks were anaphylactic in origin. In one of these attacks the patient died some six weeks after the operation.

This case is interesting because of the extrusion of the forceps through a tough, thick-walled organ like the uterus, and I have found no record of any other case in which this happened. It is also uncommon because of the long period that the foreign body remained in the peritoneum. It must have been left there either eighteen months or nineteen years before, and the longer time is suggested by the history that the pain persisted and increased after the first operation and was unchanged by the second, and also by the existence of dense adhesions at the second operation.

#### CASE II.

The second case was one in which a bone penholder was passed into the vagina by a patient who was unable to withdraw it. It remained in the peritoneal cavity from the morning of January 2nd until the afternoon of January 5th, 1915. Even under anaesthesia no scar could be found in the vaginal vault, or on the fundus of the uterus when the abdomen was opened. The penholder, with the ink stains still showing well, was found entirely wrapped up in omentum. I ligatured off the omentum containing the penholder and closed the abdomen. The patient made an uninterrupted recovery.

In discussing these two cases with my colleagues, I found that few of them had had experience of a similar accident, nor could I find much about it published, except one very valuable article by Crossen, and a few cases that had been published because they had given rise to legal proceedings.

In considering a question like the present, where negligence on someone's part comes in, it is obvious that the great majority of cases that are not the subject of legal action will never find their way into the literature at all. To get details of the unpublished cases I sent inquiries to surgeons in all parts of Great Britain. No names were asked for, but in order to obtain full, although anonymous, records, I posted printed inquiry forms with printed reply envelopes.

I wished primarily to find out what risk there is to a patient if an instrument is allowed to remain for about five or six days in the peritoneal cavity. Such a question may be of importance if the loss of the instrument is not noted until the patient has recovered consciousness or is already suffering from such a degree of shock from the operation that reopening the laparotomy incision may be attended by grave risk, and if it is desired to confirm the diagnosis and locate

the instrument by radiography before proceeding to open up the incision. Secondly, I wished to ascertain after what interval of time the foreign body usually commences to cause symptoms, if its loss is not noted. Thirdly, what its usual effect is on surrounding viscera.

Crossen gives a short tabular summary of 50 cases that he collected from the literature from 1880 to 1907. In these 50 cases the articles left behind were as follows: Forceps 41, drainage tubes 3, rings 2, Nélaton catheter, glass irrigator, scissors, "piece of instrument," and pair of spectacles, 1 each. The total of 51 instruments in 50 cases is explained by two pairs of hæmostatic forceps being left in one patient.

Many of the cases abstracted by Crossen are incomplete, and essential details are lacking, but an examination of his collected cases shows that some 24 either certainly or probably lived, 13 died, and in 13 the details are inconclusive. The time the foreign body remained in the peritoneal cavity in the cases that recovered varied from a few hours to ten and a half years, but it is of interest that in only 7 out of 24 was the period over one year.

The foreign body was removed by a subsequent laparotomy in 10 cases; removed through a sinus or abscess in 7 cases; passed spontaneously per rectum in 4 cases; removed by colpotomy in 2 cases; and once was found in the bladder. In two of the fatal cases and in four others it was stated that serious damage resulted to surrounding viscera.

In answer to my inquiries, I received details of 39 cases, including a few in which foreign bodies had been passed into the peritoneal cavity either per vaginam or per rectum. There are three specimens bearing on the subject in the museum of the Royal College of Surgeons, making 44 with the two cases already recorded in detail above.

The foreign bodies found comprised 29 artery forceps, 2 retractor blades, 2 glass rods, 2 bone knitting-needles, 2 hairpins, and 1 drainage tube, 1 towel clip, 1 uterine dilator, 1 piece of needle, 1 pin, 1 bone penholder, and 1 stone.

Of the 44 patients 11 died, giving a mortality of 25 per cent. In these 11 fatal cases the foreign body is stated to have been present for the following periods: Several years (3 cases); seven years (1 case); two years (1 case); one year (1 case); five months (1 case); three weeks (1 case); and twice "unknown."

In all cases, except those where the details are wanting, severe ulceration or erosion of the surrounding viscera was present.

Among the 33 patients who recovered cases are included in which the foreign body remained in the peritoneal cavity for seven, twelve, fifteen, and (probably) nineteen years. Of the 33 cases, 26 were treated by a second operation, and in the remaining 7 the instrument was passed through a sinus or per rectum. The operations were performed within a few hours in 5 cases, within forty-eight hours in 4 cases, within a few weeks in 8 cases, and in the remaining 9 during periods ranging from six months to many years.

A consideration of the details of the cases seems to show that, as would be expected, the best result is obtained by an immediate removal of the foreign body, if the patient's general condition will permit of a second operation. But if the loss of the instrument is not noted at once, or if the patient's general condition contraindicates an immediate second operation, there does not seem to be any grave risk in leaving it inside for a few days. A solid metal instrument does not seem to cause the onset of peritonitis so rapidly as a blood-soaked gauze sponge; and a consideration of the cases indicates that the viscera do not suffer any severe damage within a few days. A striking fact is the protective action of the omentum in surrounding the foreign body and shutting it off from the rest of the peritoneal cavity.

The frequency with which this accident occurs came as a surprise to me. I received by post details of 39 fresh cases and fifty-one forms were not returned to me at all, in spite of the fact that I especially asked for the form to be returned with a negative on it and sent a stamped addressed envelope to ensure its remaining anonymous.

It seems reasonable to think that a large proportion of those fifty-one unreturned forms must have given details of fresh cases if their recipients had returned them at all. Again, it should be noted that only surgeons at the larger hospitals were circularized, and if the records of cases operated on in cottage hospitals and naval and military hospitals could be obtained it is probable that the numbers would be again increased.

Most of the cases where any date was given occurred within the last fifteen years, so that my inquiries show that,

roughly, at least 40 of these accidents have occurred in 180 months. It is therefore desirable to consider what can be done to diminish the risk of this accident.

I have deliberately avoided all reference to sponges and swabs, and definitely asked that these should not be included in my inquiry form. But it is worth while emphasizing the protection given by the use of six or twelve yard rolls of gauze for packing off intestines and sponging, instead of using large numbers of small pieces of gauze. In having a large number of swabs counted by an assistant or nurse, the usual margin of human error exists, and this can be avoided and time saved by the use of rolls of gauze as continuous sponges.

Regarding instruments, the same principle can be applied, and the number of instruments in use, especially Spencer Wells forceps, can be reduced to a minimum, an extra supply in a separate package being kept for emergencies. Also, any instrument brought near the abdomen while the peritoneum is open should measure six inches in length, although an exception to this rule must be made in the case of needles.

To conform so far as possible to this ideal I never use towel clips; it is quite easy to fix all towels by two stitches, one at the pubes and one at the upper end of the incision. Again, it is quite easy to fix efficiently the rubber sheeting, towel, or whatever is used to protect the edges of the abdominal wall by pieces of sheet lead, 3 inches broad and 12 inches long, which can be bent round the edge of the wound. This method has long been used by Oldfield and other members of the Leeds school. The use of a Reverdin needle not only saves time but largely reduces the number of small needles in use. A Reverdin needle of suitable shape can be used satisfactorily except at the bottom of a deep wound.

In the Trendelenburg position instruments tend to roll down towards the incision, and the use of an instrument tray (such as that suggested by Bouney) with a large flange will prevent this.

While operating, all haemostatic forceps should be replaced by ligatures as soon as possible, instead of leaving them hanging on the bleeding points at the edges of the wound or within the peritoneal cavity. Any instrument that has loose parts that are liable to become detached should be avoided.

#### *Details of 44 Cases in which Instruments were Left in the Peritoneal Cavity.*

In the following list the details are given so far as possible in the words used by the reporters of the case, in the following order: The kind of instrument, the position in which it was found, the nature and date of the first operation, the symptoms produced by the foreign body, the treatment adopted and the condition of the viscera disclosed, together with any note of special interest (for example, the presence or absence of a sinus in the abdominal wall), whenever such details have been reported.

1. Short Spencer Wells forceps. Among small gut. Hysterectomy, several years before. Symptoms unknown. Enterostomy. Gut ulcerated. Whole of forceps lying in cavity of gut. No external sinus. Death.
2. Short Spencer Wells forceps. Laparotomy, several years before. Symptoms unknown. Enterectomy and anastomosis. Gut ulcerated. Whole of forceps lying in cavity of gut. No external sinus. Death.
3. Small Spencer Wells forceps. Among intestines. Ruptured gastric ulcer, many weeks before. Symptoms: Faecal fistula in caecal region. Extraction through fistula. Ulceration of ascending colon. Death from peritonitis.
4. Small Spencer Wells forceps. Partly in peritoneal cavity and partly in bladder. Ovariectomy, five months before. Symptoms like stone in bladder. Laparotomy. Bladder perforated and very dense adhesions present. Point of instrument seen during cystoscopy. No external sinus. Death from peritonitis.
5. Spencer Wells forceps (6-inch). Among small gut. Laparotomy, several years before. Symptoms: Acute obstruction. Resection of gut. Two or three adjacent coils of small gut ulcerated. Ring carcinoma of pelvic colon also found and so colostomy was done at the same time. No external sinus. Death.
6. Artery forceps (5-inch). Among small gut. Gastro-enterostomy, two years before. Symptoms: Pain, increased by taking food. Double resection of small gut. Gut perforated. Instrument detected by radiogram. No external sinus. Death.
7. Spencer Wells forceps. Position not given. Appendectomy. Date, symptoms, and treatment not given. Probably no sinus present. Death.
8. Spencer Wells forceps (5-inch). Among small gut. Ruptured ectopic, three weeks before. Symptoms: Fever, pain. Mass in pouch of Douglas. Resection of small gut. Intestine damaged. No external sinus. Death.
9. Spencer Wells forceps (4-inch). In left half of pelvis, handles pointing downward. Ovariectomy, seven years before. Symptoms:

Fever, emaciation. Discharge from faecal fistula in left iliac fossa for six months. Sinus explored and instrument removed. A portion of one handle of the forceps could not be found. Death.

10. Towel clip 3 inches long. Position not stated. Laparotomy, one year before. Symptoms unknown. Found at autopsy. Royal College of Surgeons Museum, 2393 I.

11. Hairpin. Lower abdomen. Possibly passed per vaginam. Symptoms: Pelvic peritonitis. Laparotomy for purulent peritonitis. No obvious damage to viscera. Death. Royal College of Surgeons Museum, 2343 I.

12. Spencer Wells forceps (3-inch). Below umbilicus in middle line. Ovariectomy, six weeks before. Symptoms: Point of forceps palpable through scar. Removal by laparotomy. No damage to viscera. Forceps found wrapped in omentum. No external sinus. Uneventful recovery.

13. Small Spencer Wells forceps. Position unrecorded. Removal of tumour (probably renal), eighteen weeks before. Symptoms: Rectal pain and sinus. Passed spontaneously per rectum. Recovery.

14. Spencer Wells forceps. Upper abdomen. Ovariectomy, several weeks before. Symptoms: Hard mass in upper abdomen. Laparotomy. Adhesions but no erosion of viscera. No external sinus. Recovery.

15. Spencer Wells forceps (5-inch). Pelvis. Salpingo-oophorectomy, seven years before. Symptoms: Abdominal and rectal pain. Passed spontaneously per rectum. Ulceration of rectum. Recovery.

16. Small Spencer Wells forceps. Pelvis. Panhysterectomy, a few hours before. No symptoms. Removal per vaginam. No damage to viscera. Radiogram taken. Recovery.

17. Artery forceps (5-inch). Among intestines. Caesarean section, forty-eight hours before. No symptoms. Removal. No damage to viscera. Radiogram taken because instrument missed after operation. No external sinus. Recovery.

18. Spencer Wells forceps (7-inch). Upper abdomen. Radical cure of ventral hernia, four months before. Symptoms unrecorded. Enterectomy. Ulceration of bowel. No external sinus. Recovery.

19. Artery forceps. Pouch of Douglas. Ovariectomy, six hours before. No symptoms. Removal. No damage to viscera. Instrument missed after operation and palpated by bimanual examination. Recovery.

20. Spencer Wells forceps (9-inch). Pouch of Douglas. Subtotal hysterectomy, seven years before. Symptoms: Pelvic pain. Extraction per vaginam. Ulceration of vagina. Points of forceps palpable on vaginal examination. No abdominal sinus. Recovery.

21. Small Spencer Wells forceps. Pelvis. Ileo-colostomy, six months before. Symptoms: Left iliac pain. Passed spontaneously per rectum. No abdominal sinus. Complete recovery.

22. Spencer Wells forceps. Attached to omentum. Ovariectomy, twenty-four hours before. No symptoms. Removal. No damage to viscera. Loss of instrument noticed soon after abdomen closed. Recovery uneventful.

23. Kocher's artery forceps. Among small gut. Operation for perforated duodenal ulcer, three weeks before. No symptoms. Removal. Suture of bowel. Two inches of instrument lay inside lumen of gut. Instrument only discovered by accident during radiogram of bismuth meal. No sinus. Complete recovery.

24. Spencer Wells forceps (8-inch). Lower abdomen. Hysterectomy, twelve days before. No symptoms. Removal by laparotomy. No damage to viscera. Forceps missed after operation, but patient too ill for immediate search to be made. No sinus. Radiogram on tenth day. Uneventful recovery.

25. Artery forceps (6-inch). Pelvis. Ovariectomy, nine months before. Symptoms: Febrile convalescence, recurrent abdominal pain, rectal pain and discharge. Passed spontaneously per rectum. Rectum ulcerated. No abdominal sinus. Recovery.

26. Small Spencer Wells forceps. Right iliac region. Removal of broad ligament cyst, ten days before. No symptoms. Removal. No damage to viscera. Forceps missed three hours after operation. Radiogram taken. No sinus. Recovery.

27. Spencer Wells forceps (8-inch). Pelvis. Salpingectomy, four years before. Symptoms indefinite. Removal. Severe adhesions present, but no erosion of viscera. Abdomen examined on account of haematemesis, and forceps felt through wall of lower abdomen. Radiogram taken. No sinus. Recovery.

28. Artery forceps (5½-inch). Pelvis. Hysterectomy, a few hours before. No symptoms. Removal by laparotomy. No damage to viscera. Forceps missed two hours after operation. Recovery.

29. Artery forceps (4½-inch). Lower abdomen. Ovariectomy, four hours before. No symptoms. Removal by laparotomy. No damage to viscera. Forceps missed three hours after operation. Recovery.

30. Flange of a Berkeley retractor. Lower abdomen. Hysterectomy, twenty-four hours before. No symptoms. Removal by laparotomy. No damage to viscera. Instrument missed after operation. Radiogram taken. Recovery.

31. Blade of retractor 3 inches long. Loin. Hysterectomy, fifty-four hours before. No symptoms. Removal by laparotomy. No damage to viscera. Radiogram taken. Recovery.

32. Artery forceps. Lower abdomen. Laparotomy, twenty-four hours before. No symptoms. Removal by laparotomy. No damage to viscera. Recovery.

33. Drainage tube 2½ inches long. Partly in bladder and partly in peritoneal cavity. Hysterectomy, twelve years before. Symptoms: Leucorrhoea for twelve years, cystitis for three weeks. Removal by suprapubic cystostomy. Ulceration of bladder. No abdominal sinus. Recovery.

34. Glass rod 4 inches long. Recto-vesical pouch. Colostomy, four and a half months before. Symptoms were referred to a large wound in the buttock. Removal during an operation for excision of rectum. Dense adhesions but no serious erosion of viscera. Recovery.

35. Flanged glass tube 2 inches long. Under right rectus muscle. Operation for relief of ascites fifteen years before. No symptoms except ventral hernia. The tube is still there and the patient in good health. The ascites is cured. No external sinus present.

36. Hairpin (straightened). Passing from rectum and transfixing the Fallopian tube. Possibly passed into rectum, about two months before. Symptoms: Dysmenorrhoea, rectal pain. Removal by laparotomy. Peritonitis round tube. Ulcer in rectum. No abdominal sinus. Recovery.

37. Bone knitting-needle 5 inches long. Left iliac fossa. Pushed through uterus, fifteen months before. Symptoms: Abdominal pain, increased by movement. Removal by laparotomy. Knitting-needle surrounded by omentum. No damage to viscera. Radiogram taken. No sinus. Recovery.

38. Uterine dilator 8 inches long. Below liver. Pushed through uterus four days before. No symptoms. Removal by laparotomy. No damage to viscera. Radiogram taken. No sinus. Recovery.

39. Bone knitting-needle 10 inches long. Pouch of Douglas. Possibly pushed through vagina. Symptoms: Intestinal obstruction. Removal by laparotomy. No damage to viscera. No sinus. Recovery.

40. Piece of steel needle, 1 cm. long. Appendicectomy two years before. Symptoms: Persistent abdominal sinus. Sinus opened up and needle removed. Recovery.

41. Pin. Back of broad ligament. No previous operation. Possibly swallowed. No symptoms. Removed during ovariectomy for ovarian cyst. Slight adhesions, but no damage to viscera. No sinus. Recovery.

42. Stone. Lower abdomen. Stone was accidentally forced through the rectum three days before. Symptoms: Pain. Removal by laparotomy. Recovery. Royal College of Surgeons Museum 2310 I.

43. Artery forceps (4½-inch). Left iliac fossa, perforating uterus. Two laparotomies, one eighteen months, the other nineteen years previously. Symptoms: Pain, diarrhoea, leucorrhœa. Removal by abdominal hysterectomy and suture of colon. Severe ulceration of colon present. No abdominal sinus. Radiogram taken. Sudden death six weeks later, as recorded in detail above. Royal College of Surgeons Museum.

44. Bone penholder 5 inches long. Above umbilicus, wrapped in omentum. Pushed through vagina three days before. Symptoms: Pain. Removal by laparotomy. No damage to viscera. Uneventful recovery. University College Hospital Museum.

## THE TREATMENT OF TRYPANOSOMIASIS.\*

## (A FURTHER REPORT.)

BY

CLAUDE H. MARSHALL, M.B., B.S.LOND.,  
SENIOR MEDICAL OFFICER, UGANDA;

AND

S. M. VASSALLO, M.D., D.T.M. AND H.,  
MEDICAL OFFICER, UGANDA.

CONFRONTED by the problem of the treatment of trypanosomiasis in the field, and at the same time precluded from access to any reference library, the present writers endeavoured to evolve a working hypothesis which would explain the relapses so characteristic of the disease, and on that hypothesis planned a method of treatment which at the time they thought novel, and details of which have already been published in two previous articles.<sup>1</sup> Briefly the procedure comprised an attempt to sterilize the blood stream by the intravenous injection of arsenical compounds and an immediately subsequent attempt to sterilize the central nervous system by the intrathecal injection of salvarsanized serum. When holiday leave, however, afforded opportunity of consulting the literature on the subject it became evident that similar hypotheses must have been adopted by several previous workers, notably Balfour, Van Someren, Thiroux, D'Aufreville, and Reichnow, even as far back as 1906, and the evolution of the idea can be followed by the following references.

Thiroux<sup>2</sup> suggested that the absence of trypanosomes from the blood of certain patients was due to the presence of specific antibodies; and conversely, the presence of trypanosomes in the cerebro-spinal fluid was due to the absence of such bodies.

Thiroux and D'Aufreville<sup>3</sup> conjectured that serotherapy would not give good results in meningeal trypanosomiasis

unless the antitoxin was injected into the spinal canal and cerebral substance, as had been done in tetanus.

Balfour (1903) in a memorandum, "The treatment of sleeping sickness," presented to the Sudan Sleeping Sickness Commission, drew attention to the treatment of cerebro-spinal meningitis by intrathecal injection of immune serum, and suggested a combined therapy for sleeping sickness, the trypanosomes being attacked in the blood by some of the more promising of the chemical trypanocides, and in the cerebro-spinal fluid by the injection of the patient's own serum or the serum from a case under treatment, obtained by defibrinating or centrifuging the blood.

Van Someren,<sup>4</sup> putting Balfour's suggestion into practice, treated six cases, but concluded that the results were not encouraging. He added, however, that the method was tried only in cerebral cases, usually too far gone for other treatment.

Reichnow (1914), in the Kameruns, treated his cases on similar lines, but added 0.04 gram neo-salvarsan to his salvarsanized blood serum, a procedure which he himself admitted was far from devoid of danger and the risk attendant upon which caused him to abandon the method, as other observers had already done in the treatment of syphilis of the central nervous system.

From the above extracts it is quite clear that those whose duties included the treatment of sleeping sickness in endemic areas were even then—as they are now—dissatisfied with the adequacy of the methods at their command; so that it is almost incomprehensible to the present writers that the fact that they were following (even if unwittingly) the suggestion of such a keen observer and logical thinker as Balfour should have aroused so much and so uncompromising a hostility.

Moreover, the method we now advocate is administratively and economically sound. The patient's treatment is completed in two or three days, when he is free to return to his village and friends. Large hospitals and camps are no longer required, nor is the patient's life made irksome by continuous drugging for long periods of time. The natives themselves appreciate these advantages and now come in of their own volition asking for treatment.

Recently Warrington Yorke, in a critical review of recent work on the treatment of sleeping sickness in the *Tropical Diseases Bulletin*,<sup>5</sup> has done us the compliment of massing much of the evidence he has collected from the literature around the debatable points in our work in such a manner as to make it evident that he, like ourselves, is primarily interested in the elucidation of the disease. As we have now completed a further survey of the cases we have had under treatment by various methods, we wish to present the results to the impartial reader so as to make it clear where we are in agreement with Yorke's arguments and where we consider our observations justify a totally different interpretation. But first we would deal with some general observations in connexion with sleeping sickness.

Naturally the first point that arises in connexion with the work has reference to the virulence of the particular strain or strains of trypanosomes that are met with in the Uganda Protectorate. With a nomadic population it is sometimes difficult to collect the necessary figures in support of any particular view, but we now have notes relating to the Northern Province of nearly 100 cases which have been diagnosed clinically and by laboratory methods and have been under observation for a year and a half, and another 200 cases which have been under observation for a shorter period (six or seven months). For facilities in following up these cases we are indebted to the Hon. E. C. Eliot, Acting Chief Secretary of the Protectorate.

The following table shows the course of the disease in the district under natural conditions and without treatment, and may be of value in another direction also—namely, that of extending Yorke's Table II. We have here adopted Yorke's plan of setting out the percentage mortality under two headings—in the first place assuming that all the cases missing at the time of the second census were alive, and under the second heading assuming that those missing had died of the disease. From our table it will be seen that the mortality varied from a minimum of 14.7 per cent. in one series of cases of six months' duration to a maximum of 70 per cent. in the small series under observation from twenty months. The true mortality percentage obviously lies somewhere between these extremes, but in any case the inference is justified that the disease, as it occurs in Uganda, is a serious one, and that the strain of trypanosome which is encountered there is fairly virulent.

\* This report was received on September 11th, 1922.

TABLE I.

District.	No. of Untreated Cases.	Months since first seen.	No. Alive.	No. Missing.	No. Dead.
Gulu ... ..	23	20	10	0	16
Arua ... ..	40	18	12	8	20
Toro and Katwo ...	23	18	11	8	9
East Madi ... ..	123	6	90	15	18
West Madi ... ..	118	7	73	20	25

The percentage mortality of these cases would therefore be as follows:

District.	Percentage "A."	Percentage "B."
Gulu ... ..	61	61
Arua ... ..	50	70
Toro and Katwo ...	31	60
East Madi ... ..	14.7	18.6
West Madi ... ..	21	38

Note.—The cases here shown are the cases still alive and not those "alive and well"; if only the latter were included, the percentage would be very different indeed—for example, of the 12 cases alive in Arua, 6 are in an advanced state of sleeping sickness.

The East Madi figures are by Dr. G. D. H. Carpenter, who was in that area in September, 1921; of the cases he examined then, he only noted one as being in an advanced state, yet by February, 1922, eighteen had died. Further, in the same area, another sixty cases were discovered in March, 1922, but it is difficult to say if these were recent infections or were cases that had eluded observation during Carpenter's previous tour.

It is interesting to compare the figures relating to Gulu in this table with some details of a small series of treated cases discovered about June, 1920, in the same area; apart from the 26 untreated cases recorded in Table I, 11 others were conveyed a distance of some three hundred miles to one of us (S. M. V.) and were then treated in the latter part of the year as indicated in Table II. They returned home, two advanced cases dying on the road. Owing to difficulties of transport, etc., no further observations were possible till March, 1922—that is, about fifteen months after treatment—when it was found that a third case had died, giving a mortality of 28 per cent. The remaining eight cases absolutely refused blood, gland, or any other form of examination, so that, though alive and to all appearances well, we have no definite evidence to offer as to their condition, and have therefore omitted them entirely from our calculations.

TABLE II.—Treatment and Results of the Gulu Cases.

Case No.	Date of Treatment.	Treatment.	Result.	Period under Observation.	Remarks.
40	4.10.20	Intrathecal salvarsanized serum	Died	—	Advanced cases; died on road.
41	4.10.20	Ditto	Died	—	
44	4.10.20	Ditto	Well	15	C.S.F. positive (neo-kharsivan).
47	15.11.20	Ditto	Well	14	C.S.F. negative (atoxyl).
48	15.11.20	Ditto	Well	14	C.S.F. negative (atoxyl).
49	2.12.20	Ditto	Died	—	
50	2.12.20	Intramuscular salvarsanized serum	Well	14	Atoxyl.
51	6.12.20	Intrathecal heterogenous serum	Well	14	C.S.F. negative (atoxyl).
52	6.12.20	Intrathecal salvarsanized serum	Well	14	C.S.F. negative (atoxyl).
53	6.12.20	Intramuscular salvarsanized serum (heterogenous)	Well	14	Atoxyl.
54	6.12.20	Intrathecal heterogenous serum	Well	14	C.S.F. negative (atoxyl).

If it had been possible to carry this experiment to a definite conclusion the results would have been of considerable value, since both the treated cases and the controls lived under identical conditions in an infected district, and in close contact with other cases of disease, for there is even now in Gulu and the surrounding districts a serious epidemic of sleeping sickness.

The next criticism—and a very reasonable one—that the cases we have recorded as still alive and well are not necessarily cured, cannot easily be controverted at this stage, owing to the widely varying interpretations placed upon the word "cure" by different authorities. In a discussion which followed the paper by the present writers at the Royal Society of Medicine in 1921 a five years' limit was suggested as desirable. Whilst regarding this as a counsel of perfection, we are not in the least inclined to take exception to it, and judged by this criterion we are ready to agree that all our cases are still "under observation"—although it may be noted that from time to time cases are reported in the medical press as "cured" well within this period. Hitherto, however, if clinical symptoms are totally absent and examination of the blood, glands, and, whenever possible, the cerebro-spinal fluid, is repeatedly negative within a period of two to three years, we have assumed that such an uninterrupted convalescence normally proceeds to a permanent cure. Such cases are referred to in all our subsequent tables as "alive and well."

Turning now to Yorke's criticisms, he is correct in emphasizing the fundamental character of our statement that "most authorities are agreed that although the (intravenous) administration of one dose of salvarsan, neo-salvarsan, or atoxyl may be sufficient to sterilize the blood stream, yet within a variable period, averaging about four months, the symptoms reappear and the disease progresses to a fatal termination." Table III, although it only comprises six cases that we have treated in the first instance with only a single dose of neo-kharsivan or novarsenobillon, does include some of the coincidences characteristic of the disease in Uganda which originally stimulated our interest in the treatment of trypanosomiasis.

TABLE III.—Showing Results of Intravenous Treatment Only.

Case No.	Date of Diagnosis.	Intravenous Dosage.	Result.	Period under Observation.	Remarks.
7	10.7.19	0.6 gm. neo-kharsivan.	Relapsed. C.S.F. + 27.10.19	Months. —	Re-treated completely 28.10.19. See Table I.
14	22.11.19	0.6 gm. ditto	Well	26	
28	21.4.20	0.4 gm. ditto	Well	21	
56	13.1.21	0.4 gm. ditto	Died	—	Sleeping sickness 23.9.21.
68	2.8.21	0.3 gm. novarsenobillon	Recurred	—	Trypanosomes in blood 20.1.22.
69	15.12.21	0.6 gm. neo-kharsivan	Died	—	Sleeping sickness 17.4.22.

Thus (1) in two very early cases the single dose (intravenous) apparently acted as the desired *therapia sterilisans magna* and resulted in the individual remaining "alive and well" after twenty one (Case 28) and twenty-six (Case 14) months respectively; (2) in four cases the single dose was insufficient to sterilize the blood stream and/or the central nervous system; and (3) in three of these relapse occurred in three and three-quarter months (Case 7), four and three-quarter months (Case 68), and four and a half months, when death occurred (Case 69); Yorke, too, quotes Larz as recording nine relapses out of eleven after salvarsan within one and a half months, and four out of six treated with atoxyl within one month.

Further, in many instances sleeping sickness is a disease of slow progress, and, although symptoms may reappear within a short time of one therapeutic dose, the subsequent progress may be very tardy; such, however, is not usually the case—for example, Case 56, Table III. With regard to the fatal character of the disease Yorke quotes one batch of cases undergoing various prolonged treatments (Table IV, *Bull. Trop. Med.*, 18, 1921, p. 172), which in this connexion is very significant—namely:

"Hodges, Uganda, states that of 1,185 cases admitted between December, 1906, and November, 1907, 734 were dead at the end of two years and only 49 could be found four years later, whilst 912 were known to be dead; of the 49 still alive, 27 were clinically advanced cases, 19 showed definite signs of disease, and only 3 were cases we should count as 'alive and well.'"

Other similar instances become at once apparent from an examination of Table IV, where we have completed Yorke's Table IV in this sense.

TABLE IV.

Author.	No. of Cases.	Condition before Treatment.	Treatment.	Length of Observation Period.	No. Disappeared.	No. Dead.	No. Alive.	Percentage of original total alive assuming all who had disappeared are		Remarks.	On our Basis "Alive and Well."	
								"A" Dead.	"B" Alive.		"A" percentage.	"B" percentage.

Marshall and Vassallo, 1918-1922	12	Unselected cases	1 dose neo-kharsivan 1 injection intrathecal serum	2-3½ years	2	2	8	66.6	83.0	All "alive and well"	65.5	83.0
	17	(2 advanced) Unselected cases	Ditto	18-21 mos.	1	0	16	94.0	100.0	All "alive and well"	94.0	100.0

With reference to our own cases which we have incorporated in this table we would point out: (1) Of the three cases we record as missing, two, we believe, died during the famine, while the third, we are informed, is working on an estate in a distant part of the country and is perfectly well; but as we have put the worst possible construction on our returns these "missing" do not really affect our percentage any more than those of Simson's cases who died of small-pox or cerebro-spinal meningitis. We have, however, excluded the two cases of reinfection, and the one case who died, possibly from delayed chloroform poisoning. (2) All our cases are unselected, as compared to some of Simson's returns, and the deaths occurred in very advanced cases, which would not have been included if we had exercised any selection. (3) The cases here included have only received one complete treatment—that is, one intravenous injection of arsenic and one intrathecal injection of serum the following day, as against the prolonged treatments of others—a point completely ignored by Yorke.

We would therefore suggest that this table in its present form not only affords considerable support to our first assumption, but also goes far to confirm our statement that our routine method of treatment has furnished better results than any one hitherto published treatment of a series of cases.

Again, in Yorke's Table I there are given details of 46 cases where it is claimed that (a) trypanosomes disappeared from the cerebro-spinal fluid after treatment, and (b) treated cases survived for long periods after their cerebro-spinal fluid was found to be infected. There are no details with regard to 4 cases, which leaves us 42 to deal with. Martin, Leboeuf, and Ringenbach record a series of 31 cases, and of these 11 disappeared and 10 died. Of the remaining 10, which were followed up, only 3 were found negative after twelve, nine, and seven and a half months respectively—that is, out of 31 cases under 10 per cent. were found to be negative.

Incidentally the period of observation of all these cases is much less than ours.

The other 11 may be regarded as isolated cases. Eight are examples of negative cerebro-spinal fluid after treatment when examined at intervals of one and a half to nine months, but the cell count in most instances suggests that infection is merely latent. Of the remaining 3 cases (Gray and Tulloch) one gave post-treatment positive results until his death at the end of twenty-three months, and the other two were positive up to the end of 230 and 195 days respectively. These cases are of academic interest undoubtedly, but for all practical purposes merely indicate the slow progress of the disease in some individuals.

Yorke's Table II<sup>6</sup> is interesting, as in the first two instances it suggests that the chances of infected individuals remaining alive are equal whether they are treated or not; for example, 100 per cent. (calculated on 3 cases) and 80 per cent. (calculated on 5 cases) were still alive without any form of treatment. In a third instance the information that 5 were known to be well and working after four years out of a total of 102 cases is held to justify a percentage of 33 living (Dutton and Todd). The absence of any details with regard to the number dead, number alive, and number missing would, on the basis of our calculations, give less than 6 per cent. "alive and well."

The second assumption, a threefold one, is as to its first sentence—"Quite early in the disease the trypanosomes appear to gain an impregnable position in the central nervous system"—avowedly an alternative to the "drug-fast" theory. As to its second part—"in this position they are protected from the action of drugs"—it may be remarked that syphilologists as a body fail to find arsenic in this situation after using salvarsan and its derivatives in the medicinal doses at present employed. It further derives a certain amount of support even from the personal communication from Voegtlin to Yorke (which is all that is offered in contradiction of our

statement) that arsenic reaches the cerebro-spinal fluid in low concentration only after massive and toxic doses have been administered intravenously. The further observation of Vogtliu (unpublished), "that parasites in the cerebro-spinal fluid of experimental animals diminish within twenty-four hours of large doses of these drugs administered intravenously," might, it is true, be explained by the action of that trace of arsenic in the cerebro-spinal fluid, but we would hazard another explanation more in consonance with our own conceptions—namely, that trypanolysin is formed as a result of the action of the intravenous arsenic upon the trypanosomes in the circulating blood, and this trypanolysin is then secreted into the cerebro-spinal fluid by the choroidal cells.

The third part of this assumption, supported though it is by cases in which the cerebro-spinal fluid was originally apparently sterile, but was found to be infected at the time of the post-treatment relapse (for example, Case 7, Table II), is, we are willing to admit, still lacking in experimental proof, since on this point we can only offer the experimental work of Reichnow (one observer again) that infection does take place from the cerebro-spinal fluid to the blood stream. As to the exact route, until experimental proof is forthcoming we are willing to accept either of the suggestions put forward—namely, that infections in the basal systems travel via the nerve sheaths (Keith) or via the arachnoid villi (Halliburton), since either structure, in our opinion, might be permeated by the living trypanosome just as readily as it is by the amoebic activity of the leucocyte.

Still, with regard to the second assumption, we may perhaps deal further with some of Yorke's criticisms. In the first place he argues that if there are no nervous symptoms and the lumbar puncture is negative, there is no evidence that the central nervous system is involved, and therefore it is not justifiable to tamper with it. To this we would reply that a negative lumbar puncture does not necessarily mean that the cerebro-spinal fluid is sterile; the trypanosomes might be present in so small a number as to be overlooked or even to be actually absent from the quantum of fluid taken for examination—an argument which Yorke himself advances when it serves his purposes (that is, when he suggests that relapses are due to a few trypanosomes in the blood, so few as to escape detection when the blood is examined). That the parasites have other hiding-places than in the cerebro-spinal fluid, we are quite willing to admit is more than a probability (we have already referred to van Sacheghem's work on the bone marrow); it is almost a certainty, and could be paralleled by the relapses which occur in malaria after apparent sterilization of the blood stream by drugs, under circumstances where reinfection is impossible and where there is no suspicion either from the symptoms or from the subsequent history that the central nervous system has ever been involved. In face of the well known fact that nervous symptoms are practically always the accompaniment of advanced cases of sleeping sickness, we are of opinion that the central nervous system is the seat of election. Stevenson, too, has recently demonstrated trypanosomes in the central nervous system cells.

There is, of course, the possibility that Yorke, like many others even in the present year of grace, has a personal aversion to the local treatment of infections of the central nervous system, despite the brilliant results achieved in this direction by the scientific use of suitable serums in the treatment of cerebro-spinal meningitis, tetanus, and syphilis of the central nervous system. Others have already advocated local treatment for demonstrable trypanosome infections in this situation, and more recently Mayer urges intrathecal injection of "Bayer 205" and Pearce of trypanamide. But in view of the opposition of the native to repeated lumbar punctures and the possibility of the existence of central nervous system infection at the moment treatment is undertaken, we consider it more politic to administer the drug through the needle employed to collect the specimen of cerebro-spinal fluid for examination. On the result of the subsequent examination we can decide whether we have employed the salvarsanized serum as a prophylactic or a therapeutic agent. In other words, on the clinical evidence at our disposal, we have gone a step farther than other workers, and employed the method as our routine treatment, and we have the temerity to assert that our results have justified our action.

We are now in a position to present our own results to date in concrete form.

TABLE V.—Cases Treated by Intrathecal Salvarsanized Serum and Results to Date.

Case No.	Report up to 31.1.20.		Report up to 31.1.21.		Report up to 31.1.22.

\* ? Chloroform poisoning.

Table V gives the cases treated by the method we suggest should become a routine one, with the reports at the various time periods presented on former occasions. Apart from two cases this needs no comment. We must, however, draw attention to Cases 18 and 20. These were found at a subsequent examination several months after treatment to harbour trypanosomes in their glands, but in both cases the cerebro-spinal fluid was negative.

Case 18 was treated on April 18th, 1920; three subsequent examinations were all negative: a fourth one on July 27th, 1921, showed trypanosomes in glands.

Case 20 was treated on April 25th, 1920; subsequent examinations were all negative, but on April 20th, 1921, trypanosomes were recovered from a gland by puncture.

Obviously these two cases would be claimed, by hostile critics, as instances of the failure of our routine treatment; we, however, consider them as reinfections—the only ones we have noted; the circumstantial evidence that influences our opinion is as follows:

1. The glands of both cases had disappeared after the first treatment, and there had been consistent negative results of blood, glands, and cerebro-spinal fluid.
2. There had been no clinical signs or symptoms of any sort during these twelve months, and it would therefore appear probable that the disease had been arrested at the time of the first treatment.

3. Both patients live at Nakibira, a village in the cleared part of the sleeping sickness infected area on the Mpologma River, from which place, however, a succession of fresh infections have been derived (Cases 36, 37, 66, 67, and 68).

4. Investigation showed that the people from this village were crossing to an uncleared and heavily fly-infested promontory, Budobo, for the purpose of devil worship.

5. Acting on the belief that they were not relapses but reinfections, and early cases at that, we treated them by a single intravenous injection of arsenic. Up to the present date they both remain quite well, and blood, glands, and cerebro-spinal fluid are completely negative. (Another case treated with plain serum, who also comes from Nakibira, showed trypanosomes in glands, and he also is possibly a reinfection.)

In view of a suggestion made to us by Dr. Shaw Mackenzie of King's College, that the results obtained from serum treatment might be due to the stimulation of fat splitting by the autogenous serum, we have treated a number of cases by injecting the serum intramuscularly instead of intrathecally. The number so treated, however, is too small for any conclusions to be drawn from them. Dr. Shaw Mackenzie also gave us two preparations to try—"A" and "B"—on which we are experimenting; further, he suggests that autogenous serum is one of the best stimulants of lipase.

In our endeavour to ascertain clinically the most satisfactory procedure we have used other methods; these are set out in Table VI, which is again self-explanatory.

TABLE VI.—Showing all Cases Treated, Method Employed, and Result to Date.

No.	Method.	Total Treated.	Alive and Well.	Dead or Relapsed.	Number Missing.
1	Intrathecal serum	41	31	8	2
2	Plain serum—that is, no preliminary drug injection	4	3	1*	0
3	Non-autogenous serum: injected intrathecally or intramuscularly	7	4	3	0
4	Intramuscular serum—as 1, but intramuscularly†	7	5	1	1
5	Drug only intravenously	5	2	3	0
6	Drug direct into spinal canal	2	0	2	0

\* Possibly reinfection. See report.

† See Shaw Mackenzie's suggestions.

‡ See Table II.

Towards the end of 1920 Dr. Ashton Boud of the Church Missionary Society, Toro, at our request treated some cases by the salvarsanized serum method. He writes as follows (January 31st, 1922):

"... serum (about eighteen months ago) and in most cases there was general improvement of general health and also the glands had mostly become so small as to be hardly palpable, or else were not palpable at all."

Boud has, in addition, treated 12 other cases; after an average period of twelve to eighteen months these were re-examined, and the following report sent to us about them: "Dead, 2; 'alive and well,' 5; and migrated to Belgian Congo, 5." (The latter are therefore probably quite well.)

Apart from the appended figures we have, since the beginning of 1922, treated some 200 cases at the suggestion of the Uganda Government. These we have grouped under various treatments as follows:

1. Intrathecal salvarsanized serum.
2. Intramuscular salvarsanized serum.
3. Intramuscular plain serum.
4. Intrathecal plain serum.
5. "A" (Shaw Mackenzie) intravenously only.
6. "B" (Shaw Mackenzie) intramuscularly only.
7. "A" (Shaw Mackenzie) intramuscularly only.
8. "B" (Shaw Mackenzie) intramuscularly only.
9. "B" (Shaw Mackenzie) intramuscularly only.

The study of these cases should provide an instructive commentary on the efficacy of the treatment we advocate.

We wish to express our deep obligation and thanks to Dr. C. A. Wiggins, P.M.O. Uganda, for permission to publish this report, and also for his great assistance in enabling us to

carry out this method on a large scale; also in Uganda to Drs. Mary Martin, Griffin, Bond, and Rawson; and in England we are deeply indebted to Professors Simpson and Eyre and to Dr. Shaw Mackenzie for their very valued interest and assistance.

## HISTOLOGICAL CONDITIONS IN A CASE OF ADDISON'S DISEASE.

BY  
EVELYN E. HEWER, D.Sc.,

LECTURER IN HISTOLOGY AND ASSISTANT LECTURER IN PHYSIOLOGY  
AT THE LONDON (ROYAL FREE HOSPITAL) SCHOOL OF  
MEDICINE FOR WOMEN.

It is not easy to find any detailed description of the microscopical appearance of the organs in Addison's disease; the following details may therefore be of interest, more especially in view of the prominent part that is being assigned to the endocrine organs at the present time.

**History.**—The patient was in September, 1921, he began to suffer from by vomiting, and about the same time his skin began to darken; she stated that the deep bronze colour noted on his admission to hospital was reached within a few weeks. In January, 1922, the patient gave up work, and took to his bed on account of progressive weakness; at this time he also complained of pains in his limbs and chest, and was treated for "influenza." On February 14th, 1922, he was admitted to hospital suffering from extreme weakness. He had had no previous illness except severe influenza thirty years ago. The family history is good and he has five healthy children.

**Condition on Admission.**—The patient was emaciated, although well built and muscular. He was extremely weak, and sweated freely on the slightest movement. Temperature 94° F., but no shivering. The skin was brown all over, the pigment being most marked over the hands, face, penis, scrotum, nipples, and anterior folds of the axilla; there were also brown spots within the cheeks. There was some deep tenderness over the liver; no superficial abdominal hyperaesthesia. There was slight dullness over the apex of the right lung. Knee and ankle jerks absent; flexor plantar reflex. The urine was alkaline, sp. gr. 1026; otherwise nothing abnormal detected. Respirations 20, shallow. Circulation: Radial pulse not felt; blood pressure (by auscultatory method) 55 mm. Hg; blood film normal. A blood count showed red blood corpuscles 4,800,000; haemoglobin 65 per cent.

The temperature rose to 98° F. on February 15th. On the morning of the 18th, the fourth day after admission, he suddenly became weaker and died.

### Post-mortem Report.

**Lungs:** Old pleural adhesions present over the whole of the right lung; a few scars of old healed tubercle at right apex. Bronchial glands show no evidence of tubercle. Heart: 233 grams, normal. Liver: 1,450 grams, slightly nutmeg. Gall bladder: Distended; contains a single small black stone; no evidence of inflammation. Spleen: 200 grams, moderate perisplenitis. Kidneys: 330 grams, normal.

**Suprarenals.**—Right, 16 grams; left, 22 grams. The right is small and fibrous, the left shows much fibrosis and some areas of caseating material. No evidence of accessory suprarenal tissue.

### Microscopical Appearance of Organs.

The material obtained at autopsy was fixed immediately in formal-acetic-Müller, and embedded in paraffin; the sections were stained with Scott's haematoxylin and Biebrich's scarlet, with Mallory's connective tissue stain, with Weigert's resorcin-fuchsin stain, and by the Ziehl-Neelsen method for the tubercle bacillus.

**Suprarenal.**—Only one small area of cortical tissue found involved in a chronic tuberculous process with round-cell infiltration showing an unusually high percentage of plasma cells. There was much fibrosis, some calcification, and formation of many giant cell systems. The cells of the cortical tissue were of the type belonging to the zona fasciculata, many of them spherical with strongly eosinophil cytoplasm and eccentric nuclei; other cells were very irregular, with poorly staining nuclei. The unusual appearance of these cells might have been due to post-mortem changes, but more probably indicates the breakdown of the last remnants of true cortical tissue. No medullary tissue was found. The surrounding fat was unusually rich in small round cells. A small ganglion just outside the organ showed some cellular degeneration and pigment deposition.

**Pancreas.**—No gross lesion was detected. The islets of Langerhans appeared normal, and contained some lymphocytes. The organ was extremely vascular, and there was some fibrous increase in the blood vessel walls.

**Thyroid.**—The organ was not so vascular as usual. There was very little intervesicular parenchyma, but frequent aggregations

of lymphocytes between the vesicles. Most of the latter were distended with colloid, and showed a very flattened epithelium; in these vesicles the colloid stained very deeply with Biebrich scarlet, and was probably old. A very few vesicles showed the typical cubical epithelium, lightly staining colloid, and slight vacuolation round the edge of the colloid, that indicate active secretion; these vesicles, mostly towards the outer edge of the gland, seemed the only really active ones. A few vesicles showed migration of cells into the colloid, and the appearance of giant cells; both epithelium and colloid were disappearing from these vesicles.

**Thymus.**—Some true thymus tissue was persistent, lying as nodules in fat and fibrous tissue. There was slight increase of the connective tissue elements, and large cells of endothelial type were entering the gland in parts by way of the trabeculae. A few large, clear, strongly eosinophil cells were present, and an occasional giant cell. The Hassall's corpuscles were unusually large and well formed, and a few chromophobe complexes were also present.

**Spleen.**—The capsule contained hardly any muscle, being almost completely fibrous. The pulp showed intense congestion, with hyperplasia of the endothelial cells at the expense of the lymphoid tissue. The Malpighian bodies were small, otherwise normal. A very few giant cells were present, and many eosinophil myelocytes, which usually showed bilobed nuclei. The walls of the small arteries were thickened.

**Testis.**—The condition of the seminiferous tubules resembled somewhat that obtained by the action of x rays in small doses. (This patient had never received any x-ray treatment.) There was marked degeneration of the tubules; no spermatozoa were present, but a few spermatids. In the tubules, cells of all stages of development were being set free into the lumen; some of these cells showed a large nucleus with diffuse, poorly staining chromatin; others showed a very small pyknotic nucleus. There was no mitosis. A few tubules showed giant-cell formation. Very little interstitial tissue was present; there were very few (if any) real interstitial cells, but an increase of fibrous tissue and a few large strongly eosinophil granular cells. The vascularity was not increased.

**Semilunar ganglion.**—There was definite, patchy, cellular degeneration, but no evidence of local tuberculous or other inflammation. Very few of the cells were healthy, and various stages of degeneration could be distinguished. There were cells staining poorly, showing an indistinct outline, swollen eccentric nucleus, and pyknotic nucleolus; in a later stage the nucleolus was lost and yellow pigment granules appeared in the cytoplasm; then the nucleus became vacuolated and disappeared, the cytoplasm became very granular, and much pigment was deposited; this pigment did not contain iron. The nuclei of the cell capsules were also degenerated, and some of the nerve fibres. Nissl staining showed that the basophil substance was diffused throughout the cytoplasm, even when the cells appeared healthy.

**Lymphatic Glands.**—Lymph glands from the neighbourhood of the suprarenal, pancreas, semilunar ganglion, and portal fissure were examined. They all showed subacute inflammation, but no tubercle bacilli were found. A fibrinous exudation was always present just within the capsule, and filling the periglandular lymphatic sinus. The cellular content was high, and many large endothelial cells were present, entering the glands along the connective tissue strands; there were also many eosinophil cells of various sizes, some clear, others granular. Most of the glands showed some fibrosis. No pigment was present.

**Pituitary.**—The pars posterior was more vascular than is usual and showed several small haemorrhages; there was no evidence of pigment, nor of "colloid," but small granular masses with faintly eosinophil reaction were present. The pars intermedia showed a small amount of eosinophil colloid, and a large proportion of the small strongly eosinophil cells of the pars anterior. The pars anterior had a general appearance of being normal; the small chromophobe cells were fairly numerous, but there were very few of the large basophil cells; on the other hand, the vast majority of cells were strongly eosinophil, and these were of all sizes. Some colloid was present, similar to that of the pars intermedia; and between the groups of cells, but apparently not in the blood vessels, there was much granular chromophobe (secretion). In parts some cells were greatly enlarged and swollen, with eccentric nuclei, looking as if being changed into this chromophobe granular material. There was some increase of fibrous connective tissue in the pars anterior.

The presence of the tubercle bacillus was not demonstrated in any of these organs.

Considering the extent of the suprarenal lesion, serious symptoms were of comparatively short duration. At the time of death there was probably no functioning suprarenal tissue, and yet the patient had been at work until three weeks before this.

It has been stated that in Addison's disease there is a general increase of lymphocytes; in this case no such increase was apparent. The blood picture was normal; in the spleen the lymphoid tissue was even decreased owing to the increase of the endothelial cells. In such lymph glands as were examined the cellular content was certainly high, but in addition to the increase of lymphocytes there were also many endothelial cells. But a general lymphoid increase was not apparent; this is contrary to the distinct increase that the author obtained in rats whose suprarenals had been almost destroyed by inoculation with certain suprarenal constituents.

It is to be regretted that no haemolymph glands were obtained for examination, because in the experiments just referred to melanoblast cells—carrying pigment presumably produced consequent on the deficient elaboration of adrenin—had been found in these glands. In the case under discussion such cells were not found in the organs examined; no doubt melanin-bearing cells were present in the Malpighian layer of the skin, as is usual in this disease.

The thymus evidently reacted to the condition in the same way as the other lymph glands, as shown by the appearance of endothelial cells. The large Hassall's corpuscles and chromophobe complexes are usually interpreted as signifying involution of the gland; this is what would be expected in a man aged 42. The condition of the thyroid is interesting in connexion with the view that this gland and the suprarenal mutually excite each other's activity. In this case the suprarenal was probably functionally inactive, and the thyroid presented an appearance similar to that seen in colloid goitre, with very few indications of any activity. The degeneration of cells in the sympathetic ganglia in this disease has been emphasized by others; it may perhaps be due in part to the lack of adrenin, which is necessary for the optimum functioning of the sympathetic nerve endings.

The atrophy of the seminiferous tissue in the testis is of interest in view of the debated relationship existing between the suprarenal cortex and the gonads. In this case both seminiferous and interstitial tissue were degenerating. Here again the breakdown of the tubule cells was precisely similar to the degeneration experimentally brought about in rats by suprarenal inoculations (where again the suprarenal was more or less destroyed), and is probably due to perverted or deficient action of suprarenal autotoxins.

It is often stated that there is a close functional relationship between the suprarenals and pituitary. In this case the suprarenals were probably functionless, and the pituitary had the appearance of great secretory activity. It is somewhat difficult to interpret the appearance of a "fixed" human pituitary; the *post-mortem* changes are rapid, and various fixatives have very different effects on the cells. The extension of colloid material into the pars anterior, and the presence of masses of granular chromophobe material, probably signify great activity; it is, however, unusual to find the colloid strongly eosinophil, and the relative number of basophil cells was below the normal.

I am greatly indebted to Dr. A. P. Beddard, under whose care the case was, for permission to make use of the hospital reports from which the above details of the history of the case and the gross *post-mortem* findings have been taken, and also for permission to publish this case. I would like also to thank Dr. Laidlaw for procuring the material for me, and Professor Herring for examining the sections of the pituitary.

## TWO CASES OF HORSESHOE KIDNEY.

BY

CLIFFORD MORSON, O.B.E., F.R.C.S.,  
SENIOR ASSISTANT SURGEON, ST. PETER'S HOSPITAL.

The union of both kidneys by means of fibrous tissue is a well known abnormality, generally recognized in the *post-mortem* and dissecting rooms, Sir Henry Morris claiming that it occurs in one out of every thousand bodies. But when the uniting band is composed of renal tissue the condition is believed to be of unusual interest and undoubted rarity. The cases which I record come in the latter category, and the interest of one is enhanced by an accurate diagnosis having been made during life with the assistance of pyelography.

### CASE I.

The patient, a man aged 45, had suffered from a stricture of the urethra for many years, which from time to time had been dilated with instruments. When this man came under my care, apart from difficulty in micturition, he complained of pain in the left loin. A skiagram revealed the presence of a shadow in this region, but as I was not convinced that it was in the left renal area I decided to perform pyelography. The pyelogram clearly showed the presence of an accessory calyx directed inwards from the lower pole of the left kidney towards the vertebral column. It also demonstrated a shadow immediately above that of the accessory calyx and distinct from it. The renal pelvis was shown to be dilated, but no calyces other than the one mentioned could be seen, the explanation of which was not cleared up until after the operation.

Under general anaesthesia an incision was made in the left lumbar region and the kidney exposed. It was found that the convex border of the kidney was resting on the quadratus lumborum,

the pelvis looking forwards and slightly inwards. This position explained why no calyces other than those of the uniting portion of the renal tissue could be seen in the pyelogram, the shadow due to the dilated pelvis lying immediately in front of the kidney.

All attempts at delivery of the kidney on to the surface of the loin failed, owing to the lower pole being attached to the opposite kidney. The bond of union could be felt as a thick mass extending across the middle line immediately in front of the aorta and inferior vena cava. The successful removal of the calculus, which was embedded in the lower pole, presented difficulties on account of the lack of mobility of the kidney, and an incision had to be made through the capsule and cortex before the stone, the size of a marble, could be extracted. The patient's convalescence was slow, but no complications occurred until six weeks later, when an outbreak of influenza in the ward caused pneumonia to set in, from which the patient died.

The post-mortem examination revealed a very fine example of a horseshoe kidney. (See Fig. 1.) The left half of the transverse portion was anatomically perfect—that is, it consisted of calyx and cortex, the latter seen with the microscope to be made up of glomeruli and tubules. The right half had no calyx, but normal glomeruli and tubules were present. Each half of the uniting band of renal tissue had its own blood supply, which was distinct from that of the kidneys proper. The ureters, as is usual in these cases, passed down in front of the kidneys. Both pelves were dilated, the left more than the right.

In order to confirm the presence of an accessory calyx, as seen during life in the pyelogram, and before a portion of the uniting band had been removed for microscopical examination, a post-mortem pyelography was performed. The accompanying illustration (Fig. 2) shows the result of this procedure. The accessory calyx and the dilatation of the renal pelvis are again well demonstrated, but branching shadows can also be seen in the cortex of the left kidney. These shadows are caused by the pyelogram fluid having been injected under pressure, and forced into that part of the cortex where incision was made for removal of the calculus.

Since this specimen was shown at a meeting of the Section of Urology of the Royal Society of Medicine, I have had to operate on a somewhat similar case at the Whipps Cross Hospital. The notes of the case are as follows:

#### CASE II.

The patient, a man aged 33, had had intermittent attacks of pain in the left loin from childhood. No investigation of the urinary tract had been undertaken until recently, when cystoscopy was performed at one of the London hospitals. The patient, having refused any further examination, was discharged, but later was admitted to the Whipps Cross Hospital. Again he refused any examination, but was willing to undergo an operation if promised that he would be relieved of his pain. As a fluctuating swelling could be felt in the left loin extending down to the left iliac fossa, I felt confident of the diagnosis of hydronephrosis without the necessity of confirmation by pyelography. As indicating pressure on the inferior vena cava the superficial veins of the lower limbs and lower abdomen were noted to be dilated. Previous to the commencement of the operation, when fully anaesthetized, the patient was cystoscoped. The bladder and ureteric orifices were normal. A catheter passed up each ureter and ureteric orifices were normal. The quantity of urine which escaped from the left side was greater than that from the right. The urine analysis prior to operation

showed a urea excretion of 2 per cent. and the absence of abnormal constituents.

On exposure of the left kidney through an incision in the anterior abdominal wall the diagnosis of hydronephrosis was verified. Its

removal was not possible until some of the fluid contents had been evacuated, this being accomplished by means of trocar and cannula. Two and a half pints of straw-coloured fluid were thus drawn off. From this bag of urine two small stones were also removed. Separation of the surrounding tissues from the kidney then revealed a band of renal tissue 1½ inches broad, extending from its lower pole across the aorta and inferior vena cava and continuous with the lower pole of the opposite kidney. The latter in size and consistency felt normal. The left ureter and left spermatic vein, which were anterior to the uniting band, were ligatured and divided. With great care this transverse band was next dissected off the aorta and divided between two ligatures of Japanese gut. No accessory calyx was observed. The ligature of the vessels of the renal pedicle was attended with some difficulty owing to their unusual arrangement. In fact, no pedicle as such existed, both arteries and veins having entry and exit along the entire

length of the inner border of the kidney.

The operation was followed by profound shock and paralytic distension of the small and large bowel, but these disquieting phenomena disappeared under appropriate treatment carried out by the resident medical staff of Whipps Cross Hospital. The dilated veins of the lower abdomen and limbs subsided within a week of the nephrectomy. From the first the function of the remaining kidney was satisfactory.

It has been stated that in cases of horseshoe kidney an occasional symptom is epigastric pain due to pressure of the transverse band on the aorta. It was absent in both of my cases. Moreover, I am sceptical of such an explanation should there be complaint of pain in this region. The first structure to show signs of pressure must be the thinner walled inferior vena cava, and then the sympathetic nerve trunks in its vicinity.

A careful search of the literature on the subject of horseshoe kidney has not elicited any reference to the presence of accessory calyces in the uniting band, as dia-

gnosed by means of pyelography. I have reason to believe, therefore, that the pyelogram of the first case is unique.

THE United States Census Bureau states that in 1921 the death rates of mothers from childbirth and puerperal causes were lower in 1921 than in any year since 1917. In the area for which figures are available the death rate in 1921 from puerperal causes was 6.5 to 1,000 live births, and the ratio of deaths from childbirth to the number of women bearing children in the year was about one to 150.

THE *Nederlandsch Tijdschrift voor Geneeskunde* states that the sixth All-Russian Congress of Internal Medicine was held in Petrograd last September under the presidency of Professor Kotschalowsky of Moscow; 500 members were present, and 104 communications were made. Moscow has been chosen for the next meeting in 1927. The fifteenth All-Russian Surgical Congress was held the same week in Petrograd, and was attended by 685 members. There were 158 communications.

FIG. 1.—Drawing of horseshoe kidney, showing the position of the bloodvessels, which supply the uniting band of renal tissue, also the ureters passing down in front of it, and the dilatation of both pelves.

FIG. 2.—Post-mortem pyelogram. Note the shadows of the accessory calyx and those in the cortex. The pelves of both kidneys are dilated.

## MILK INJECTIONS IN INFANTILE COMPLAINTS.

This case here reported may be of interest, for although the diagnosis may be open to question the treatment was followed by immediately satisfactory results.

At the local maternity hostel Mrs. W., at 11.30 p.m. on September 25th, 1922, gave birth to a male child weighing 7 lb. 10 oz. The confinement was normal, but forceps were employed at the end on account of feeble uterine contractions; no force was needed. During the first two days the baby passed a considerable amount of blood in its stools, and on the third day I was prepared to inject haemoplastin, but found that the bleeding had ceased after a dose of castor oil. Haemoplastin was therefore not given.

As the mother had no milk the baby was put on citrated cow's milk, which appeared to suit it quite well. When a week old, on October 5th, it began to have convulsions; at first infrequent and slight, they soon became frequent and very pronounced. In one night as many as thirty fits were observed. On October 8th the diet was changed to Nestlé's milk with cream added, and he was given 1 grain each of bromide and chloral regularly; the only result observable was that he was drowsy between the fits, which were just as frequent. He never vomited, nor did he seem to be in discomfort. The convulsions went on for a whole week, and showed no signs of stopping. The questions which arose were: What was the cause of the convulsions? and what treatment should be adopted? It did not seem probable that the brain had been injured during birth, for the labour was easy, while there had been no fits until the first week had passed.

There were no indications that the milk was not being digested, or that it was in any way unsuitable; but the idea that the child had in some way been sensitized by the protein of the milk gradually became a conviction. About noon on October 12th I boiled a little milk in a test tube and injected 10 minims into the child's thigh. The fits were worse down to about 7 p.m., after which they gradually eased off, and by 6 a.m. on October 13th they had ceased entirely, and down to the present, three months later, another fit has not been observed. For the day or two following the injection of the milk there was a considerable inflammatory reaction in the thigh, which was hard and tense, but subsided.

I must leave it to others to decide whether or not anaphylaxis was the actual cause of the fits in this case, and whether the injection of milk desensitized the child. I record the case as I do not remember having come across one similar, and the result was spectacular.

Harrow.

W. A. WILSON-SMITH, M.D., D.P.H.

The result of the method of treatment adopted in the following case was very striking, and may be found useful in similar cases of infantile diarrhoea.

A baby girl was born on November 2nd, 1921; she weighed 6½ lb., and was perfectly healthy. She was fed by the mother, and things went well for three days; but on the fourth day icterus neonatorum appeared, and the stools became dry, chalky, pale yellow in colour, and increased in frequency, until on November 9th twenty or more were passed in twenty-four hours. The character of the stools now altered; they were loose, watery, with mucus and streaks of blood in them. The child became restless and lost weight, in spite of careful treatment. The parents were greatly alarmed, as the first baby, a boy, had died of exactly the same symptoms a year previously.

On November 12th 1 c.c. of sterilized mother's milk was injected subcutaneously. The effect was remarkable. The patient, who was peevish and restless, slept for ten hours at a stretch. The number of stools dropped to five during the next twenty-four hours; but they were still loose and slimy. On November 14th a second injection of 2 c.c. of mother's milk was given. The diarrhoea stopped, and within forty-eight hours the stools became normal. The child rapidly gained in weight, and is now alive and well.

The mother's milk in the above case was abnormally rich, thick, and yellowish in colour, and the infant was unable to digest it. The subcutaneous injection produced a lasting tolerance, and the child has now gone through her first year of life unusually free from trouble.

## VENESECTION IN A CASE OF APHASIA.

VENESECTION is so rarely performed nowadays that the following case is, I think, both interesting and instructive.

The patient is a man aged 52, who had been treated by me some nine years ago for pancreatic diabetes, but had been lost touch with during the war. There is no history of syphilis. On January 3rd, 1923, I was called to the patient, who had gone to bed on

feeling "queer" soon after the midday meal. His face was congested, his mouth drawn to the left, and his speech more or less incoherent, although he was quite conscious, knew what he wanted to say, and was annoyed when he used wrong words. He had vomited, but was not in pain, nor was there any apparent loss of power or sensation. The temperature was normal; pulse 72, regular, and somewhat "full." The blood pressure was not taken, as I considered other action more urgently necessary. The heart was normal in size and situation and there were no adventitious sounds. Eye movements were normal; pupils of medium size, equal, and reacted briskly to light; fundi normal. Knee-jerks normal. The urine contained large amounts of both sugar and albumin.

I decided that this was a case in which blood-letting was indicated, and at once opened the left median cephalic vein and relieved him of three-quarters of a pint of blood. The effects were immediate and gratifying. His complexion improved, the vomiting ceased, and he began to recover his proper speech. Subsequent progress was no less satisfactory. He was placed on a strict diet, which was amplified at the end of a week, and given other treatment.

The patient says he feels quite well, though weak. His speech is normal, and though his mouth still droops a little on the right side he can whistle and laugh without difficulty or deformity. He is going about the house, but not yet taking an active part in his business.

[Since the above was written he has developed albuminuria retinitis.]

London, W.

R. GALWAY MURRAY, M.D.

## Reports of Societies.

## THE TREATMENT OF GASTRIC AND DUODENAL ULCER.

A MEETING of the Hunterian Society was held on January 29th at the Mansion House, with the President, Dr. FORBES FOX, in the chair. In opening the meeting the President said that this was the first occasion during the Society's long connexion with the City of London on which it had met in the official residence of the Lord Mayor, and he expressed its great sense of obligation for the privilege.

SIR BERKELEY MOYNIHAN delivered the second Hunterian lecture on the treatment of gastric and duodenal ulcer. It is published in full in this issue at page 221.

In the subsequent discussion Dr. J. R. BELL (Leeds) said that the method of fractional gastric analyses was of comparatively recent introduction into this country, and the interpretation of the curves obtained was by no means complete. It had been the custom to describe typical curves for different conditions, the most notorious example being the so-called duodenal ulcer curve—a rapidly rising curve with continued secretion. But in a series of Sir Berkeley Moynihan's cases this curve was found in only 5 per cent. of those with duodenal ulcer, showing how very fallacious the statistics based on particular curves might be. He believed that there were almost no curves which could be said to be typical.

MR. H. W. CANSON said that the principle that cases should not be turned over to the surgeon until a long course of medical treatment had been tried was likely to lead them astray; medical treatment of chronic gastric ulcer was likely to be useless. The present tendency in operation was to be more and more drastic, and partial gastrectomy offered itself as the recognized procedure; mere excision was not sufficient, nor, he thought, Balfour's operation. He did sleeve resection for a particular type of callous ulcer over the lesser curvature; though it sounded a formidable operation, patients stood it very well.

DR. CAMPBELL McCLEURE thought Sir Berkeley Moynihan had been a little hard on medical treatment; it required patience and endurance on the part alike of doctor and patient. The idea of starving a patient for a few days and then hurrying him on to a moderate diet shortly after the disappearance of the symptoms was ridiculous. He agreed that the treatment of chronic gastric ulcer, once the diagnosis was thoroughly established, should be surgical. He was glad to hear the question of gastrectomy pushed; anything which would avoid gastro-jejunostomy was to be encouraged, for it was a horrible makeshift.

MR. GORDON TAYLOR said that he was becoming more and more an ardent advocate of partial gastrectomy, the results of which were extraordinary. There were certain cases of gastric ulcer where the haemorrhage would not cease in spite of medical treatment. He had ten cases of gastric ulcer

associated with severe haemorrhage, and performed partial gastrectomy, with nine recoveries; they were all very large ulcers.

Dr. RAMSAY (Tasmania) spoke in admiration of the technique he had studied at Sir Berkeley Moynihan's clinic, and said that he would carry back to Australia very pleasant memories of some excellent surgery.

Mr. J. H. ROBERTS also spoke in support of partial gastrectomy, which, he said, was followed by no symptoms—a result that could not be claimed for any other form of operative treatment. Mr. A. MORTIMER WOOLF referred to the extreme importance of diagnosis. In both duodenal and gastric ulcer the most important indication in diagnosis was obtained from the clinical history, which could only be elicited by good temper and great care. The PRESIDENT (Dr. Fox) remarked that in recent epidemics of influenza symptoms indistinguishable from duodenal trouble were often observed, and he had known operations for perforated duodenal ulcer necessary after influenza.

Sir BERKELEY MOYNIHAN declared that he had never said or thought that a gastric ulcer could not be compelled to heal. The scars—seen rarely at operation, more frequently in the *post-mortem* room—indicated with certainty that a chronic gastric ulcer had healed. All his efforts that evening had been directed to the encouragement of the physician so to supervise, and especially to protract, his treatment as to secure such a result. His own sympathies were really medical. After all, the craft of surgery was a thing within the capacity of most men who took pains. But the things within the purview of the physician were illimitable and infinitely more interesting. Surgery, bereft of medicine, was work for anybody. Surgery with medicine in it was, in his judgement, the greatest pursuit in the whole world. Physicians found fault with gastro-enterostomy, but there was no fault to be found with that operation; the fault was with the people who practised it in cases in which it was utterly inadequate. Gastro-enterostomy was quite useless—he could assure them, because he had seen it practised—in the vomiting of pregnancy. It did not relieve—and again he spoke from what he had seen—the gastric crises of *tabes dorsalis*. It was not of very much use in cases of carcinoma of the colon. In such cases and in many others he had known the operation of gastro-enterostomy to be practised. But in the right kind of case and, done in the right way, there was no operation in surgery which was better than gastro-enterostomy, and when physicians criticized it—as they had every right to criticize an operation, seeing, as they did, the surgical dust heaps—he would ask them rather to criticize the choice of that operation for a condition for which it was unsuitable. He had performed sleeve resection and was not very dissatisfied with it. He had seen it performed also on the Continent, to the satisfaction of some distinguished surgeons, though, they admitted, with occasional bad results. He had no quarrel with the operation; but it was a great thing to have ideals—ideals were not so much for attainment as for pursuit—and he himself was chasing the ideal of an absolutely perfect operation for patients suffering from chronic gastric ulcer. In his hands, and in the hands of those trained by him in Leeds, they had no fault to find with gastrectomy, and they found blemishes in every other method—not serious blemishes, but something short of perfection. Not long ago he was spending a week-end in Liverpool with Robert Jones and Harold Stiles, and the question arose as to what was the greatest weight he had ever seen put on by a patient after gastrectomy. He replied that he thought some patients had almost doubled their weight. But on reaching home that day he saw a new patient who was accompanied by another lady, and the latter by certain gestures and glances indicated that he ought to know her. He searched his mind in vain to identify her, and when at last she told him who she was he flatly denied it, saying that he knew that person very well. But having given him some convincing proofs that she was the person in question she consented to be weighed, and he found that if she had only put on seven pounds more she would have trebled her weight as it was before gastrectomy was done. He said to her, "You cannot blame me for not recognizing you. You see, I had not seen two-thirds of you before!"

In conclusion Sir Berkeley said that the things which made a surgeon's life worth while were not the things that he got for himself. They were not the titles he received nor the money he accumulated, nor the books he wrote. He had perpetrated a few literary efforts himself, and had been profoundly dissatisfied with every one of them. The thing that

made the surgeon immortal was the spirit he imparted to the teaching of the men who were coming after, and he thought that Mr. Gordon Taylor, who knew the work in Leeds, would say that he had been the means of training some young men who could do these things just as well as he could himself, if not better. The legacy that he had always wanted to leave to posterity was a band of young men trained by him and inspired by his spirit, and he ventured to hope that that was one of his dreams which had come true.

On the motion of Mr. T. H. OPENSHAW a hearty vote of thanks was accorded.

## CARDIO-VASCULAR CONDITIONS IN RELATION TO ANAESTHESIA.

At a meeting of the Section of Anaesthetics of the Royal Society of Medicine on February 2nd, with Dr. A. L. FLEMING in the chair, the relation of some cardio-vascular conditions to anaesthesia was discussed.

Dr. J. STRICKLAND GOODALL spoke on the systematic examination of the patient in a cardio-vascular case. He admitted that the methods he described would be impossible in a large number of cases where, owing to the patient's condition, the examination had to be of the most superficial character. The ideal, however, was always to discover the exact state of the cardio-vascular system, and thereby minimize risk. It would not be long before every general hospital would have a proper cardiological department, under a trained cardiologist, where every case would be examined as a matter of routine before operation.

The examination of the cardio-vascular system included the examination of the heart, the vasomotor mechanism of the vessels, and the respiratory pump. It was advisable to examine the patient three times: standing, lying, and after exercise. The face of the patient was instructive. They all knew the typical mitral face, and the difference in appearance when the cardiac condition was good and when there was failing; also the pale face of aortic disease, the dull yellow face of infective endocarditis, and the absolutely pallid face of pericarditis. If the patient was cyanosed one would look at his neck to see what the jugulars were like, at his fingers to see whether they were clubbed, and so forth. If the apex beat was visible its regularity or irregularity must be noted. On palpation the position of the apex beat and its character could be made out. A "slapping" apex beat meant that the ventricle did not contract well, either because it was degenerated or was subject to some toxic condition, or was not sufficiently stretched by adequate filling. A "heaving" beat meant only one thing—namely, ventricular hypertrophy. A third apex beat was made up of two distinct components, "slapping" and "shoving," and was almost always characteristic of a double lesion. If the apex beat was irregular the volume of the pulse would enable one to distinguish whether this was due to auricular fibrillation or extra-systole. If there was an intermittent thrill it was important to find out under what conditions it was intermittent.

On auscultation the quality of the first sound at the apex was important. The normal first sound was long, dull, and booming. This sound indicated the condition of the muscle and of the auriculo-ventricular valves. It might be short in any condition which interfered with the contractility of the ventricle. A reduplicated first sound meant a disturbance of the relationship between pulmonary and systemic pressure, as in mitral stenosis and arterio-sclerosis. The apex beat might be weak, or suppressed, or modified by the presence of a murmur. He believed that the systolic murmur at the apex, if of endocardiac origin, always meant leak through the mitral valve. The second sound of the apex might be distinct, duplicated, or modified by the presence of a murmur. At the base the aortic second sound was particularly interesting; normally it was short and sharp, but if accentuated it meant a high peripheral resistance and high blood pressure; if ringing and metallic it meant damage to the structure of the aortic valve. The aortic second sound was weak when the valve was inflamed; or it might be duplicated owing to inflammatory or degenerative change. Its absence did not necessarily mean that the aortic valve had not closed, but only that it closed so quietly as not to be heard. There were several different means of assessing the quality of the first and second sounds. The differential stethoscope was sometimes useful, and the electrocardiograph gave a graphic record of what the myocardium was doing at any particular time.

The worst hearts, from a myocardial point of view, in which an anaesthetic could be given were cases in which there was profound myocardial toxæmia, or definite degeneration of the myocardium. In aortic cases observation would be made of the vasomotor mechanism, which should be tested first for vasomotor stability and then for positive and negative vasomotor accommodation. He spoke in conclusion of the heart in Graves's disease, where the heart underwent a progressive degeneration. Cases of Graves's disease which died during or after operation were those in which the ventricular myocardium was damaged.

Sir BERNARD SPILSBURY said that for a number of years he had been very much interested in the subject of deaths under anaesthetics, and had had unusual opportunities of investigating cases. In 1913, in a Section of the International Congress of Medicine, he gave an analysis of 104 cases in which death occurred during or shortly after the administration of the anaesthetic. In all these cases he made the *post-mortem* examination himself. The anaesthetic employed was chloroform alone in 58, chloroform in mixture in 22, pure ether in 12, and other general anaesthetics in smaller numbers. The cases in which death was found associated with the condition of status lymphaticus numbered 32. In almost all these 32 cases a microscopic examination showed fatty degeneration, sometimes of the acute patchy type, easily recognizable in the *post-mortem* room, at others of a diffused fine type, giving rise to a pallor or sometimes a glazed appearance of the heart muscle, which was liable to be disregarded. In some of the remaining cases, although death had taken place under the anaesthetic, the anaesthetic was not the cause of death.

During the last nine years (1913 to 1922) he had studied 174 similar cases, which he had not been able to classify as completely. In this series the status lymphaticus cases numbered only 26—a considerable drop in proportion to the whole number. Quite a large proportion of these status lymphaticus cases were in the early years of life—8 out of the 26 in the first five years. In a certain proportion of cases, again, the anaesthetic probably played no part in causing death, and in some the cause was quite evidently pulmonary embolism or serious hæmorrhage. In certain cases the patient was moribund when administration commenced; this was particularly so in cases in which storaine was administered. In 9 cases storaine was administered alone, and in 3 others it preceded some other anaesthetic, but all these patients were desperately ill at the time. In 56 cases pure chloroform had been used, and in 56 others chloroform mixtures, in 36 ether alone. In 10 per cent. of the cases nitrous oxide had been given, either alone or with ether, but these cases, again, were desperately ill. He systematically investigated the condition of the heart muscle in almost every case of the 174, and found fatty degeneration or brown atrophy or a combination of the two conditions in all but a very few (three or four). In four cases the anaesthetization had been of an exceptional character. One was a case of murder by the administration of chloroform; the victim was a healthy boy, and there was no disease of the heart muscle. Another was a case of suicide by inhalation of chloroform, and here there was a certain amount of brown atrophy. The other two were apparently accidental deaths, one of a chemist and the other of a nurse, both caused by the breaking of a bottle of chloroform, and in both there was a certain amount of disease of the heart muscle. Among the 174 cases there was not one in which there was fibrosis of the heart muscle; only one in which there was disease of the coronary arteries; only one in which there was pericarditis, and that of slight degree. In 5 there was valvular disease, and in 3 congenital disease of the heart, all in young children, who had other diseases also. Of cardiac lesions which were seriously important in connexion with the administration of anaesthetics, diseases of the myocardium took the first place; these pointed, in the vast majority of cases, to some toxic process, either chronic, as in the status lymphaticus cases, or acute, and the damage to the heart muscle, caused by this original poisoning, was extended up to a fatal result owing to the additional poisoning action of the anaesthetic.

Dr. GOODMAN LEVY said that there seemed to be a consensus of opinion among anaesthetists that, provided the circulation was not seriously disturbed, no cyanosis or marked dyspnoea being present, inhalation anaesthesia was generally a safe procedure in cases of cardiac disease. Yet if fatality should occur there was a tendency to impute responsibility rather to the state of the heart than to the anaesthetic.

Recent information as to the mechanism of chloroform syncope must lead to an entire recasting of ideas on the relation of cardiac activities to this disease. So long as chloroform was regarded only as a cardiac depressant, and every case of syncope as a manifestation of an overdose, it was perhaps permissible to draw an inference as to correlation between chloroform syncope and cardiac disease. It happened, however, that the condition underlying chloroform syncope—namely, fibrillation of the ventricles—was essentially a manifestation of the healthy heart. In fact, a heart with depressed muscular action was less excitable, and hence less liable to pass into ventricular fibrillation, than a heart with a healthy muscle. Ventricular fibrillation also was less likely to occur when the blood pressure was low. There was no evidence that endocardial lesions or muscular degenerations predisposed in any way to chloroform syncope.

In the general discussion Dr. JOHN PARKINSON commented upon the absence of any rapid heart stimulant, though it was true that the conditions of heart failure were not alike, and it was improbable that one remedy, if it could be found, would meet all conditions. There were only two common irregularities—auricular fibrillation and extra-systole. Dr. Goodall looked rather more seriously on extra-systole than other cardiologists; current opinion was that extra-systoles, apart from other signs, had little significance. Mr. JAMES BERRY spoke on the value to the operating surgeon of electrocardiography and examination by a skilled cardiologist. In exophthalmic goitre cases particularly there ought to be free consultation between cardiologist, surgeon, and anaesthetist. There were two classes of cases in which, if he were operating with a young and inexperienced anaesthetist, he was a little fearful: one was the case of a fat and flabby person, whether he had a murmur or not, and the other the case of a person with advanced malignant disease, especially when there were cancerous glands at the root of the neck. Dr. JOSEPH BROMFIELD said that the cases in which anaesthetists did want all the help which could be given to them were those cases in which the heart was degenerated or toxically affected, and in which there were no apparent signs to arouse suspicion beforehand.

Dr. GOODALL, in reply to a remark by Mr. BERRY, said that he did not believe in local anaesthesia in Graves's disease, nor in any condition which was to a large extent an "emotion disease." Adrenaline, injected into the circulation, would produce ventricular fibrillation. With regard to extra-systole, he thought it extremely rare to find this condition, which was an expression of hyperirritability, without some other associated evidence of cardio-vascular disease.

## A REVIEW OF EPIDEMIOLOGY.

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine held on February 2nd the President, Dr. R. J. REECE, C.B., delivered his inaugural address on "Progress and problems in epidemiology." Dr. Reece first described the aims of the founders of the Epidemiological Society, and pointed out that, although many of the most important papers in the *Transactions* were the work of men who had not served in the medical service of the State, the early days of the society were those of the activities of Simon, Netten Radcliffe, George Buchanan, and others, the value of whose epidemiological work could not be overrated. When the State Medical Department was transferred to the newly constituted Local Government Board in 1871, other men joined the service, and the study of epidemiology was continued by Power, Thorne-Thorne, Ballard, Barry, Parsons, T. W. Thompson, Theodore Thomson, Bulstrode, and many others whose names were household words in this society. He continued:

"Only last year one of our members, who joined the society in 1887, departed from us—my old colleague Robert Bruce Low, who, by his industry, skill, and perseverance, materially assisted in the advancement of our knowledge in regard to the prevalence and distribution of disease throughout the world. In a sense he continued the work which is out the world. In a sense he continued the work which is specially associated with the name of Netten Radcliffe. While he held a strong view on many subjects, he had only one opinion, and that an honest one; and he was able to keep an unbiased mind, for he loved truth for truth's sake. His amiable disposition, courteous manner, and his readiness at all times to place his knowledge and experience at the service of his medical brethren, endeared him to all."

When the society was founded it advocated adequate endowment for medical research and, Dr. Reece thought,

they might congratulate themselves that with the advent of the Medical Research Council one of the primary objects of the society had been fulfilled. He next sketched the career of Sir Patrick Manson, who was a firm believer in the influence of the Epidemiological Society for good in promoting the study of epidemiology, and in his presidential address, in 1900, set forth the future lines of research to be followed.

"During the twenty-two years," continued Dr. Reece, "that have elapsed since Manson delivered the address there has been considerable stimulus in the study of pathology and bacteriology, sciences that directly improve our knowledge of epidemic disease though not of the epidemicity of disease. Many workers have entered these fields of study, but it cannot be said that there has been any comparable influx of workers in the domains of epidemiology. There are few men who have the time and opportunity to devote to this science, and however rich the reward that may fall to the successful worker from the fact that he has materially assisted in advancing knowledge and in affording relief to suffering humanity, it is nevertheless a sad truism that judged on the sordid basis of finance there are other branches of medicine that are more remunerative. To be able to work men must be able to live, and to be able to live necessitates the possession of the essential means of supporting life."

The President then reviewed the salient features of certain diseases communicable from other animals to man. Speaking of anthrax he said:

"For many years it has been known that the infection can be acquired by man through handling specifically infected skins. An instance occurred during the war in which Professor Tulloch of Dundee, then a lieutenant in the R.A.M.C., found *Bacillus anthracis* in the cerebro-spinal fluid of a man who was thought to have died of cerebro-spinal fever, and on continuing his investigation he was able to demonstrate that the infection had been acquired through the respiratory tract. By so doing he added another link to the chain of evidence that anthrax is one of the diseases that is air-borne. A more recent instance in connexion with anthrax which is of interest is that of a man who died of anthrax, and who, immediately prior to his fatal illness, had been engaged in unloading bone meal from a vessel in one of the London docks. Colonel P. G. Stock, who investigated the matter, was able to produce evidence that certain samples of the bone meal obtained from the cargo of the vessel were infected with anthrax, and the question at once arises whether the sporadic outbreaks of anthrax that occur among animals in this country are associated with the use of bone meal for manure."

Dr. REECE next dealt with the present position of plague, and remarked that with the disappearance of rats from vessels the possibility of plague being ship-borne from port to port became remote. He then reviewed the general epidemiological position of zymotics, emphasized the need of further research on general epidemiological lines, and concluded his address with the following words:

"Progress in the study of epidemiology is closely associated with precise observations in the wide realm of nature, and in the correct interpretation of these observations. This requires time and opportunity, patience and perseverance, enterprise and experience. There is nothing new or startling in this statement: it is 250 years since Sydenham wrote, 'true practice consists in the observations of nature.' The student in epidemiology can in all humility echo the avowal made by Placastorius 440 years ago—'I am well aware that it is difficult to say what Heaven does effect and in what fashion, and to find a certain assured cause for every event.'"

On the motion of Sir WILLIAM HANER, seconded by Dr. E. W. GOODALL, a vote of thanks to the President for his address was carried by acclamation.

### CONCEALED ACCIDENTAL HAEMORRHAGE TREATED BY HYSTERECTOMY.

At a meeting of the Edinburgh Obstetrical Society held on January 10th, with the President, Dr. LUMOND LACKIE, in the chair, Dr. Wm. FORDYCE and Dr. R. W. JOHNSTONE read a note on a case of concealed accidental haemorrhage treated by hysterectomy.

The patient, aged 34, was seven and a half months pregnant, and had previously given birth to four children. At her first labour she had had eclampsia and severe albuminuria, which cleared up

after the pregnancy. In each of the three subsequent pregnancies she developed albuminuria about the sixth month, but the condition was kept under control by treatment, the pregnancies going to term, and the child in each case being alive and healthy. In each case also the albumin disappeared completely soon after the labour. During her present pregnancy the urine had been repeatedly examined by her doctor and no albumin was ever found, the last examination being September 22nd. A week afterwards she was still apparently in perfect health, but on the morning of October 1st she was awakened by severe abdominal pain accompanied by sickness. The pain was chiefly over the appendix region, though there was tenderness over the whole abdomen. The pulse was slow, the temperature subnormal, and there was no oedema, and apart from pallor, which was more or less her usual habit, there were none of the usual signs of haemorrhage present. She was rather short, so that it was difficult to estimate the degree of tension of the uterus or the exact size of the uterus. The os was quite closed and rigid. About 8 oz. of darkly stained urine was drawn off, which was practically solid with albumin. This, together with the sickness, the slow pulse, and the fact that the pain became localized to the epigastric region, led at first to a diagnosis of impending eclampsia. Under treatment for this the patient seemed at first to improve, but in two hours her pulse rate had steadily increased and a brownish haemorrhagic discharge appeared from the vagina. A diagnosis of concealed accidental haemorrhage was then made and abdominal section was decided upon. While preparations were being made for this a copious vaginal haemorrhage occurred.

On opening the abdomen a considerable quantity of blood-stained serum was found. The uterus, which did not seem unduly tense, was of a bluish or purplish colour, like that of an ovarian cyst with a twisted pedicle with numerous haemorrhagic patches and a large haematoma in the right broad ligament which seemed to extend subperitoneally deeply into the pelvis. Supravaginal hysterectomy was performed, the patient appearing to progress favourably thereafter, and four days after operation the urine was completely free from albumin. After a somewhat prolonged recovery due to the development of a stitch abscess, phlegmasia alba dolens, and parotitis, she was preparing to go home at the end of six weeks when she suddenly became very ill and died from what was thought to be a slowly developing thrombosis of the pulmonary artery.

On opening the uterus it was found that the placenta had been almost completely detached by a large blood clot behind it, some of it recent, most of it older. On microscopic examination the separated portion of the placenta showed evidence of early infarction, crowding and congestion of the villi, and coagulation of the intervillous spaces. In many areas the whole muscular wall of the uterus was ploughed up by the escape of blood from the vessels. In some areas there were large haemorrhages separating the muscle bundles, while in others the haemorrhages were smaller and had caused separation of the muscle fibres. There was also considerable degeneration of muscle fibres, varying in degree, but showing itself for the most part in the loss of nuclear staining. Here and there, there was some fragmentation of the muscle fibres, which had a clear hyaline appearance. The findings did not throw any clear light upon the relationship between concealed accidental haemorrhage and albuminuria.

### Gonococcal Infections of the Tubes and Ovaries.

Mr. DAVID LEES read a communication entitled "Some observations on gonococcal infections of the tubes and ovaries." He condemned the practice of promiscuous douching in gonorrhoea, and emphasized the importance of local therapy of the lower genito-urinary tract as a means of preventing ascending infection. In acute inflammatory gonococcal cases absolute rest should be enjoined, and the original focus of disease sought for and treated whether or not operative measures were employed for the treatment of such complications as salpingitis. Removal of one or both tubes was only the removal of the end-product of the disease and not a cure of the existing infective process in the rest of the genito-urinary tract. The infected uterus, cervix, and lower genito-urinary tract were still the seats of active disease and the patient continued to suffer ill health as a fertile source of infection to others, and the disease might at any time flare up or give rise to other metastatic lesions, such as arthritis. Operation was rarely needed to save life and had the serious disadvantage that it sterilized the patient if both tubes were removed, whereas there was ample evidence to show that quite a number of such cases if treated by conservative measures made a good recovery and the tubes retained their function. The main principles of expectant treatment were rest in bed with liquid diet, and an ice-bag over the lower abdomen except during menstruation, when hot applications were preferable. The bowels should be well opened, belladonna or atropine sulphate given in fairly large doses, and sedatives such as bromides or hyocyamus administered. The Fowler position assisted drainage from the uterus. Vaginal douching should be avoided while the pain was severe. When the acute abdominal symptoms had subsided hot antiseptic hip baths and careful local treatment of all foci of infection in the

lower tract should be carried out. Large vaginal douches at 112° F. helped to produce hyperaemia, prevented formation of adhesions, and hastened resolution. As soon as the temperature had subsided, usually about the second or third week, the patient should be given the benefit of fresh air, but exercise should be avoided. In addition to local treatment of the cervix and lower tract at this stage the insertion of vaginal ichthyol and glycerin tampons every second day was of benefit. Treatment through the blood stream by vaccines, detoxicated or otherwise, was essential in inaccessible lesions such as salpingitis, in order to make certain that the infection was eradicated from the tissues.

#### Pathological Specimens.

Dr. HAIG FERGUSON showed two specimens: (1) A large gangrenous submucous fibroid complicated by double pyosalpinx, acute appendicitis, and purulent peritonitis in a married woman aged 46, who had had an offensive vaginal discharge with pain in the lower abdomen for two years; panhysterectomy and appendicectomy was followed by a good recovery. (2) A cystic fibroma apparently growing in the broad ligament and unattached to the uterus, bearing a close resemblance before operation to an ovarian cyst, and during operation to a cervical fibroid. The patient was a multipara aged 42, and for three weeks before operation the tumour had been growing rapidly. It was shelled out of its capsule, and the uterus removed by supravaginal section, along with both ovaries and tubes.

#### IRISH HOSPITAL FINANCE.

The Section of State Medicine of the Royal Academy of Medicine in Ireland met on January 12th, with the President, Dr. T. HENNESSY, in the chair, when Dr. HORACE LAW read a paper on hospital finance. He said that in spite of the deficit incurred during the war the hospitals of Dublin were not in serious debt. For many years past, however, the annual income had not balanced the expenditure and was supplemented by bequests which were used as income. He sketched the development of the Board of Representatives of the Associated Dublin Hospitals, which had been engaged chiefly in studying the means of increasing income. The ideal method, he believed, was for the people to subscribe small weekly sums when well, so that the hospitals might care for them when sick. An agreement with one of the branches of the Irish Transport and General Workers' Union had been made embodying this principle, and a system of payments by urban and rural sanitary authorities for necessitous patients coming from their areas was in force in connexion with about sixty of these bodies. Arrangements had also been made with the National Health Insurance Commissioners whereby the approved societies might include hospital benefit as one of their extra benefits. Under the scheme of the Board of Representatives the patient had free choice of hospital, the payments being made by the Board to each hospital in proportion to the work done in treating patients. While acknowledging the economy and increased efficiency which would result from amalgamation of hospitals, he thought the matter at present impossible of achievement. Further, he pointed out that the smaller hospitals permitted of the patient being individualized, with the result that the patient subsequently took an interest in "his hospital."

Sir JOSEPH GLYNN said that State control would kill the hospitals, and should only be accepted as the last possible expedient. There were two ways in which the question could be approached: First, the rate in aid, which would come through the county councils, but he was not in favour of this scheme: if any one of the twenty-six counties stood out there would be difficulties. Secondly, the grant in aid, the scheme which he thought the better—and which was used in connexion with child welfare schemes at present working in Ireland. Incidentally he was of opinion that some of the hospitals in Dublin could make claims on that scheme. He thought that for every £1 which was raised by contributions, fees, or any other means for the hospitals, £1 should be given by the State, up to 50 per cent. of the annual expenditure of the hospitals.

Sir JOHN MOORE said that one point which was worthy of consideration was the proposal of a State grant to provide equipment for the hospitals, which was a very expensive item, and one which he thought should hardly be a charge on the voluntary subscription-lists of the hospitals.

Sir JAMES CRAIG said that he personally opposed State aid where State aid meant State control. He had heard the Minister of Home Affairs give a very explicit account of lotteries for hospitals. No matter how much control the Government exercised, they could not tell how much fraud went on in connexion with these. The Minister said that he would not allow these lotteries to go on unless a bill was brought in by some private member legalizing lotteries in connexion with charitable institutions.

Dr. R. J. ROWLETTE said that some years ago the hospitals came to the conclusion that they were admitting, and treating free of charge, patients who were well able to pay for their maintenance, and they therefore decided that all patients should contribute as far as they were able to the funds of the hospital. Some of the members of the various hospital boards had thought that this payment by patients would mean a gold mine to the hospitals, and in his opinion they had encouraged it too much. He had suggested long ago that if the hospitals relied too much on payment from patients they would injure both the patients and the hospitals. There was one question which had not arisen here yet, but which would later on, in connexion with payment from the patients. The British Medical Association had said that a definite proportion of the funds which were contributed by the patients towards the maintenance of the hospital should be placed at the disposal of the hospital medical staff. If the hospitals were not charitable institutions there would be no claim on the medical staff to give their skill and time free to these institutions.

The President said that the Dublin hospitals were worthy of support, and of the usual charitable donations which they had received in the past, but they were also worthy of a grant from the State. Very few of the hospitals in Ireland were fully equipped to carry out either surgical or medical work in a really efficient manner, and some of the country hospitals had been closed, with the direst consequences to the people. The British Medical Association had given this subject a great deal of consideration, and had approached it from the medical point of view. Patients admitted to hospital should come under three classes: (1) free or indigent patients, (2) tariff patients, and (3) paying patients.

A MEETING of the Obstetrical Section of the Royal Academy of Medicine in Ireland was held on January 19th, with the President, Dr. BETHEL SOLOMONS, in the chair, when Dr. L. CASSIDY read a paper on pelvic pain from a gynaecological standpoint, which was followed by a discussion. Dr. J. F. CUNNINGHAM demonstrated Kielland's obstetric forceps, which were smaller and lighter than the usual forceps, and were being used increasingly in Vienna. Dr. J. T. SIMPSON showed two urethral calculi, which had caused dystocia. Dr. L. CASSIDY said that he was of opinion that the obstruction was probably caused by the fullness of the bladder, an opinion with which Dr. SOLOMONS agreed.

A CLINICAL meeting of the West Kent Medico-Chirurgical Society was held at the Miller General Hospital, Greenwich, on January 12th, with Dr. E. W. FARMER in the chair. Dr. HILDRED CARLILL showed three cases: (1) A man who suffered from encephalitis lethargica and syphilis of the nervous system; he was unable to wash his face, his features were expressionless, and he had diplopia with unequal pupils. He was treated with one-hundredth of a grain of hyoscine twice a day. (2) A man, 53 years of age, who suffered from tabes dorsalis, with Charcot's disease of the tarsus, and lightning pains in a lower limb amputated ten years ago. His lip was thought first to be sarcomatous and then tuberculous. His pupils were unequal, the ankle-jerk was absent, pressure on the tendo Achillis was not painful, the knee-jerk was present, and there was analgesia of the ulnar nerve. (3) A boy of 13 years, who flexed his neck and spine whenever he spoke; he was able to say a few words without doing so by taking a deep inspiration between each word. Dr. E. P. CUMBERBATCH showed (1) a case of pigmented mole treated by fulguration, and (2) a case of epithelioma of chest treated by diathermy. Dr. ARTHUR DAVIES showed a man of 24 years who was fat, short, with scanty hair, and sexually normal, the underdevelopment being presumably due to polyglandular insufficiency. Dr. E. F. SMITH showed (on behalf of Mr. C. A. JOLL) two cases: (1) A man who had suffered from appendicitis six years previously, a fistula developing which required two operations for its excision. (2) A man aged 21, with the appearance of a boy of 12 years; x-ray examination showed neoplasm of brain; he had been treated with 5 grains of thyroid extract daily.

## Reviews.

### THE POISONS AND CHARM CURES OF MALAYA.

A second enlarged edition of Dr. JOHN D. GIMLETTE's book on *Malay Poisons and Charm Cures*,<sup>1</sup> of which the first appeared in 1915, has now been issued. He writes with authority, for not only has he spent more than twenty years in Malaya, but he has had very unique opportunities for obtaining information; the late Sultan of Kelantan was kind enough to depute the Secretary to the Kelantan Ecclesiastical Council and two of the medicine men to the Royal household to assist Dr. Gimlette in preparing the second edition of his book. In a foreword Sir William Willcox mentions that the Government of the Federated Malay States has given its support to the publication of the book, and points out that a large proportion of the poisons and drugs mentioned are potent substances with unknown active principles, so that they offer a promising field for research. Dr. Gimlette's book will interest many classes of scientists; it is of value to the anthropologist in that it gives an accurate first-hand account of native folklore, much of which is of a secret nature, and it is of very great interest to the pharmacologist for the reason mentioned by Sir William Willcox. It is not surprising to learn that the first edition was used extensively as a reference book in poison trials in the Malay States.

The book is chiefly concerned with the work of the "bomors," or medicine man, who is an important figure in Malay society. Clinical medicine and magic are closely allied in Malaya, and the medicine man deals in both. The origin of the magic employed is complex; it has its foundations in the original animistic beliefs of the Malays, and upon this stock have been grafted both Brahmin and Mohammedan superstitions. The final results are charms and incantations of a purely pagan nature, commencing and ending with prayers to Allah, a compromise being thus established between the ancient folklore and the newer creed of Islam. The "bomors" are of various classes: some are simple village medicine men, others are priest-physicians and masters of the occult sciences, whilst a few are dangerous characters who specialize in poisons. Dr. Gimlette describes in detail various interesting charms, incantations, and spells, some of which, he says, are secret, being known only to a limited number of "bomors."

The greater part of the book is devoted to a description of the various poisons in use in Malaya. About twenty animal preparations are mentioned which appear to contain definitely toxic substances; these are chiefly derived from poisonous fishes, toads, and insects.

The vegetable poisons of Malaya are numerous and potent; some are well known to European medicine—for instance, *Croton tiglium* (croton oil), the upas tree, *Antiaris toxicaria*, and the upas climber, *Strychnos tieuti*, the active principle of which is brucine.

In addition to these a considerable number of very potent substances are described by Dr. Gimlette which are new to European medicine. Malaya is indeed extraordinarily rich in vegetable poisons; the poisons used by the wild tribes on their arrows are in many cases complex preparations; as many as thirty different substances are known to be employed by the various tribes for this purpose. The arrow poisons are very deadly, and it is stated that five arrow wounds suffice to kill an elephant.

Criminals show a considerable ingenuity in choice of poisons. The harmlessness of powdered glass is recognized, and it is seldom given alone. Numerous vegetable poisons are employed. Several specimens of datura are known which contain hyoscyne, and these plants are used to produce stupefaction. The plant is burnt beneath the bamboo huts, and the fumes are stated to produce unconsciousness; this device is used by thieves.

It is, however, interesting to learn that in spite of the immense variety of unknown and potent vegetable poisons, criminals employ largely the common minerals arsenic and potassium cyanide. The ancient device of treacherously killing a guest by poisoning one side of a knife is known in Malaya: the knife is smeared on one side with potassium cyanide and honey, and the poison is administered during the cutting up of a water melon. The antidote for cyanide poisoning is complex, since it contains the helmet of the

soft-billed hornbill, the tusk of an elephant, and the bones of a dugong. This mixture is almost more surprising than a formula in modern polyglandular therapy.

### EPILEPSY.

EPILEPSY, though a disease which can never fail to attract attention or to demand relief, is accorded in many textbooks only the most conventional description. Hence we welcome Dr. CESTAN's monograph,<sup>2</sup> for the wider the experience of the observer the more fully is he impressed by the complexity of the disease and the difficulty of its treatment. Dr. Cestan gives a good account of the various forms of epilepsy, both those which are symptomatic of some underlying disease and that peculiar disorder known as idiopathic or essential epilepsy. The clinical features of the epileptic attack, both the grand mal and the petit mal, are carefully and fully described. Next the peculiar features of the Jacksonian, or, as our French colleagues term it, the Bravais-Jacksonian, attacks are considered and their significance discussed. In a chapter on the mental disorders which may complicate the disease, the so-called psychic equivalents and the varieties of the post-epileptic state receive careful attention, the subject being illustrated by many valuable clinical cases. A short but useful chapter on its medico-legal aspect, especially in relation to criminal responsibility, is of great interest at the present time.

The differential diagnosis between hysteria and epilepsy is often not the relatively simple matter the author would have us believe; the truth of this is indeed well illustrated by an admirable anecdote of Trousseau's quoted by the author. Very debatable ground is traversed in the brief section on the pathogenesis of the epileptic syndrome, and we may regret that so little is said as to the possible relations of abnormal "protein sensitivity" in this disease.

The epileptiform attacks occurring in cerebral lesions, both traumatic and other, are adequately described, as well as those forms found in various states of toxæmia, such as uræmia and eclampsia. The various theories as to the etiology of idiopathic epilepsy and its relation to infantile convulsions are fully discussed, and practical deductions of value for prognosis and treatment are made. The concluding section on treatment is good and concise and commendably free from prejudice. We note with interest the author's favourable opinion of the value of luminal, or gardenal, as it is termed in France.

Perhaps the author might have insisted more on the fact that every epileptic is a law unto himself, and that every case should be studied strictly on its merits, especially in regard to treatment. Little reference is made to the claims of those who urge the value of psychotherapy, but whether this omission is due to conviction or to lack of knowledge we know not. Altogether a very readable book, it cannot be said to teach the profession anything new. But as a monograph to supplement the ordinary textbook for the student we have nothing but praise for it.

### THREE TEXTBOOKS OF DERMATOLOGY.

Of making many books there is no end, especially in America. What is more remarkable is that America, with but a little help from this side of the Atlantic, appears quite able to absorb them. Here are three noble volumes devoted to the science and art of dermatology, each of which has succeeded in living beyond its initial edition; one of them, Schamberg's, has now attained its fourth. There is a very considerable similarity between these books. They each take as their province the whole of the subject, and thus a large proportion of each is composed of second-hand information culled from the works of previous writers, to whom each of the authors duly acknowledges his indebtedness. Consequently the personal note, which is so valuable and makes a textbook so much more interesting, is only occasionally heard. Each work is profusely illustrated with photographs, most of them quite good, and with a few coloured plates, which are not so good. Moreover, although the illustrations are of different patients, the authors have selected cases of such similar characteristics that the pictures would be quite easily interchangeable between the volumes. Each adopts substantially the same classification, that of Hebra, which was originally entirely pathological but lately has been modified by modern discoveries of the etiology of many dermatoses.

<sup>1</sup> *Malay Poisons and Charm Cures*. By John D. Gimlette, M.R.C.S., L.R.C.P. Second edition. London: J. and A. Churchill, 1923. (Demy 8vo, pp. 240; 24 illustrations, 8s. 6d. net.)

<sup>2</sup> *Les Epilepsies*. By Dr. R. Cestan. Paris: F. et J. Flammarion, 1922. (Cr. 8vo, pp. 275. Fr. 7.50.)

especially of infective conditions. Each is well and clearly printed on nice thick smooth paper, and they are all published at about the same price, which is somewhere between £1 and £2.

No revolutionary doctrines will be found in any of them, but each is pretty well up to date and abreast of the latest advances which have been made in the subject. Owing to modern facilities for travel dermatologists in every country have frequent opportunities of meeting one another, and consequently they, as a rule, come to a common decision on most points, and there is not much room left for marked differences of teaching on important matters. This common standpoint does not, however, prevent most dermatologists from producing textbooks of the subject, which in consequence are sound enough but distressingly devoid of originality. Sometimes, when they consider the number already before the medical public, their consciences compel them to apologize for the new arrival in the inevitable preface, and they next proceed to point out that they have produced something unlike all its predecessors. But an unprejudiced student of dermatological literature is often hard put to it to discover the novelty claimed.

Of the three volumes now before us Dr. ORMSBY'S<sup>3</sup> is the biggest, chiefly because he devotes more attention than the two others to the literature of the subject, the references are fairly copious, and he has attempted a complete treatise on the subject. In fact his book bids fair to become a serious rival to Stelwagon's well known work, but at present it is not so complete. In the study of tropical dermatoses American dermatologists have a certain advantage over their British brethren, for the tropics lie almost within their own borders and they are not, as we are, dependent for their material for observation on chance sea-borne cases. All the authors whose books are now under consideration have availed themselves of their facilities in this respect, and one of them, Dr. HAZEN,<sup>4</sup> has made a special study of skin diseases as they are seen in the negro; for this he has enjoyed exceptional opportunities, for he practises in Georgetown, District of Columbia, which is not far from the old slave states. The chief peculiarities seem to be that the skin of the full-blooded negro is more resistant to external irritants than that of the white man, though the mulatto does not enjoy this relative immunity; acute forms of irritant eczema are not so frequent in negroes, and the common septic disorders—impetigo, boils, and abscesses—are neither so common nor so severe. Psoriasis is rare and lichen planus infrequent. More interesting still is the fact that cutaneous carcinoma is comparatively uncommon, owing probably to the fact that even in the aged negro who has spent most of his life in the open air the senile degenerative changes manifested by scaly dry spots are almost unknown. On the other hand, keloid is well known to be more common among negroes than whites, and so is leucoderma. Syphilis also is more common among negroes, but this is probably due to economic rather than racial causes.

The most distinguishing feature of Dr. SCHAMBERG'S book<sup>5</sup> is the large amount of space he gives to the eruptive fevers. He is evidently one of those favoured dermatologists who have had exceptional opportunities for studying them. Most dermatologists have had to surrender that portion of their subject to the superintendents and other medical officers of fever hospitals. His article on small-pox is particularly full and interesting. He also has a useful section on x-ray treatment. It appears that in America the Sabouraud pastille, for some reason or other, probably atmospheric, does not register properly. Hence the Americans have been compelled to work out an electrical formula for timing the exposure. As the ordinary gas tube cannot be relied upon to give always the same dose under the same conditions American dermatologists are almost obliged to use the Coolidge tube for treatment since that, up to the present, is the only tube which gives uniform results. Dr. Schamberg's work, of course, is well known to all dermatologists, and his name will always be associated with the peculiar pigmentary disease of the skin called after him. In this volume he demonstrates his modesty by devoting only a very few lines to its description. He might justifiably have given more, for since he first described it other observers

have shown that it is by no means so uncommon as was thought at one time. Some of his other sections are a little scrappy—that, for example, on drug eruptions, one of the most important subjects in dermatology for the general practitioner.

In conclusion, it may be said that from each of the three books here dealt with the student or practitioner may gain a sound knowledge of the subject so far as it is possible to do so from a textbook, but, as we began by stating, there is no really outstanding feature about any one of them.

### THE EVOLUTION OF CONTINUITY.

DR. DAVID RUSSELL, in his book *The Evolution of Continuity*,<sup>6</sup> has set himself the task of demonstrating that one evolutionary principle rules throughout all nature, and that, true to this principle, all matter has been evolved into being, and the many fundamental species of dead and living matter have been differentiated. He contends also that the outstanding phenomena of living growth and reproduction reflect the action of the common factor behind all evolution. For the purpose of his thesis, as there is no such thing as absolute continuity of matter in the natural world, the word "continuity" is used to express that more or less firm attachment of component elements which resists the forces making for their severance or dissipation into wide discontinuity. Thus he explains, "the atom preserves the relative continuity of its system of revolving electrons, the living cell its protoplasmic continuity, and our bodies their cellular and tissue continuity." Though maintaining that the underlying principle is the same for all forms of matter Dr. Russell devotes the greater part of his book to the evolution of the living species and the development of the theory that this is based on the fundamental evolutionary principle, the evolution of continuity. His view seems to be that though the general principle of natural evolution is on an unshakable basis, the bed-rock of the process has never been clearly displayed, mainly because all investigators have hitherto accepted the dictum *Natura non facit saltum*. Dr. Russell believes that nature does take leaps, small and large, and that modifications of type must essentially be always sudden. Unless we mistake his meaning, his contention is that though a more perfect geological record would provide invaluable information, yet, unless his theory is accepted, there would always be large gaps in the chain of evidence, "missing links" which could only be satisfactorily explained by the view that nature in the course of evolution had never seen fit to forge them.

The author formulates four fundamental laws of growth: 1. All growth is a manifestation of the forces of attraction and repulsion in action. 2. Fertilization produces multicellularity. 3. Environment produces continuity. 4. Continuity produces arrest, and, with arrest, control—that is, the power to maintain, arrest, or release from arrest. A breakdown of the control system entails the complete discontinuity of the individual's parts, the loss of identity, death. He traces the application of these laws from the lowest forms of life to the higher and more complex forms. He explains the formation of abnormal growths or tumours as being due to the action of diverse agencies which cause an initial break of cellular continuity whereby the normal process of cell arrest is broken. In working out his theory Dr. Russell combats the Darwinian view that the variation to which must be attributed the origin of subspecies may be due to a variety of causes; he holds that variation has been acquired from environment only, and that the acquisition must have been sudden. He sums up his main argument thus: "All characters have originated as acquired variation under the influence of environment. Life itself originated as an example of such variation."

Dr. Russell's opinions are expressed in such a thoughtful and scholarly manner that they at least merit the careful consideration of biologists.

### THE COURSE AND PROGNOSIS OF PHTHISIS.

IN a small book on the cure of pulmonary tuberculosis, Dr. R. BURNAND deals not with the diagnosis, nor with the pathology, nor even primarily with the treatment of phthisis, but with the clinical course of the disease followed from the outset

<sup>3</sup> *A Practical Treatise on Diseases of the Skin*. By Oliver S. Ormsby. M.D. Second edition. Philadelphia and New York: Lea and Febiger. 1921. (Med. 8vo, p. xiv + 1166; 448 figures.)  
<sup>4</sup> *Diseases of the Skin*. By H. H. Hazen, A.B., M.D. Second edition. 1921. (Med. 8vo, pp. 8vo, pp. 608; 240 figures. 37s. 6d.)  
<sup>5</sup> *Diseases of the Skin and the Eruptive Fevers*. By J. F. Schamberg. London: Henry Kimpton. 1922. (Roy. 8vo, pp. 626; 265 figures. 25s. net.)  
<sup>6</sup> *The Evolution of Continuity in the Natural World*. By David Russell, M.D. London: George Allen and Unwin, Ltd. 1922. (Demy 8vo, pp. 278; 95 figures. 16s. net.)  
<sup>7</sup> *La Guérison de la Tuberculose Pulmonaire*. By Dr. R. Burnand. Paris: J. B. Baillière et Fils. 1923. (Cr. 8vo; pp. 193. Fr. 6.)

to its arrest or fatal termination. It is a subject which is quite inadequately treated, even in pretentious textbooks, and, though there is nothing original in the matter, the author has succeeded in bringing together into a small compass a considerable amount of information scattered through original papers and memoirs not readily available to the general reader. Tuberculosis is different in many ways from other diseases: it is one in which a cure in the sense of a *restitutio ad integrum* does not take place, while often the best that can be hoped for is the establishment of an equilibrium between the patient and the invading bacillus. He emphasizes this point very carefully. He points out that though tuberculosis may be the most curable of chronic diseases, it is also the most chronic of curable diseases, and that therefore prolonged treatment continued diligently and conscientiously for the rest of the patient's life is essential if the primary arrest is to be maintained. This is especially important as those who are clinically cured of the disease tend gradually to lose their immunity, and unless particular care be taken as to the hygieno-dietetic mode of living serious relapses may occur even after several years. This somewhat gloomy view of the prognosis of tuberculosis he supports by extracts from the statistics at Leysin.

The main portion of the book is occupied with the actual study of the progress of the disease, considered from a clinical standpoint. Accepting Bard's classification, Dr. Burnand divides pulmonary tuberculosis according to its anatomical seat of attack—that is, as to whether it affects the parenchyma, the interstitial tissue, the bronchi, or the pleura. Any case of phthisis referred to one of these categories—which are, of course, amplified—tends to evolve along a certain definite line, so that a case primarily of caseous type will tend to remain caseous, one of a chronic fibrosing type will tend to retain its tendency to fibrosis, and so on. It is the more or less distinctive autonomy of each of these classes which he then proceeds to describe. Passing on, he deals with individual symptoms, and indicates the amount of weight which is to be attributed to each in judging the condition of the patient. Great stress is laid on the limitations and the difficulties in interpretation of auscultatory findings. These at best furnish a knowledge of the local lesion in the lung, but they can afford no idea as to the general resistance of the body. The effect of therapeutic measures on the progress of the disease is considered briefly and the criteria of recovery laid down. In his opinion, speaking generally, it is unwise to pronounce the word "cure" till the patient has been free from all signs of active tubercle for a year—a year, too, in which he has returned completely to his normal mode of life. We have every confidence that this book will be of considerable value, especially to those whose knowledge of the disease is limited by their lack of experience in following its course. In recommending it to our readers we feel that it is only necessary to point to the distinguished name of its author, Dr. Burnand, the Medical Director of the Leysin Sanatorium, to ensure its welcome reception.

#### RENAL AND GENITO-URINARY DISEASES.

*Reins et Organes Génito-urinaires*,<sup>9</sup> by MM. BRAULT, COTTET, MICHON, LEMAIRE, LOUSTE, and HAZARD, is the thirteenth volume of the treatise on medical pathology and therapeutics appearing under the direction of Emile Sergent, L. Ribadeau-Dumas, and L. Babouneix. Ideas concerning the kidneys, the physiology of urinary excretion, and the pathology of nephritis are in such a state of flux that any work which gives a precise and clear view of the subject is to be welcomed. In the volume under review the task of making a survey of this interesting portion of the field of medicine has been entrusted to Drs. Brault, Cottet, Michon, Lemaire, Louste, and Hazard. The subject is difficult; no one can look at the literature on, say, the classification of the different forms of nephritis without being impressed by the great divergency of views. So is it with such subjects as the estimation of renal function, the pathology of uraemia, and the relation of vascular to renal lesions in certain forms of nephritis. The sympathy of any reviewer must, therefore, be extended to authors grappling with such subjects. It cannot, however, be said that those responsible for the volume have succeeded. The reader loses himself amongst a mass of facts, and when he lays down the volume will probably have no clearer view of

renal pathology than he had when he started. It is indeed difficult to know exactly to what class of student the volume will appeal. To the ordinary medical man who has made no special study of the genito-urinary system and its diseases it will provide stiffer reading than he is prepared to tackle. For the expert urologist it presents deficiencies that will prevent it from being of any more value, for it cannot be regarded as a work of reference. The literature on which it is based is almost entirely French; little reference is made to the work of foreign authorities.

In the second part of the work are sections dealing with diseases of the genital system, both male and female, whilst the third part is devoted to the analysis of urine. With the exception of some figures in the last section, the book is entirely without illustrations. In this respect it differs from some of the other volumes, notably the excellent volume by Legoux and Papin on urology, but the presence of a few more suitable plates and diagrams would have done much to make the reading of this volume an easier task.

#### AN INCOME TAX GUIDE.

*The Income Tax Guide*<sup>10</sup> issued by Messrs. Nelson has been prepared by a competent writer on proper lines, and is published at a reasonable price. Mr. SULLEY's service as an inspector of taxes has evidently shown him what is expected from such a handbook; for instance, he includes in his survey that separate application of the law and practice to the manufacturer, the tradesman, the professional man, the employee, etc., which is the help usually found to be most effective, but which is seldom if ever supplied at so low a price. Indeed, the matter is carried even farther, seeing that the chapter on the professional man's difficulties is subdivided, and those of the doctor, the lawyer, the clergyman, and others are dealt with separately.

The author's official experience is drawn upon to supply useful hints; his plea for accuracy in detail—"Round figures should always be avoided; they are officially suspect"—carries force, and his *obiter dictum* on the attitude of General Commissioners towards appeal proceedings might well be remembered by intending appellants—"that body dearly hates to have long or frequent sittings and to have to listen to small matters." The section dealing with the doctor includes a model form of account, with a specimen list of working expenses, for ascertaining the average liability, beside other information which should prove useful. Such matters as the adjustments obtainable where one person succeeds to a practice carried on by another, the procedure for obtaining repayment, and so on, are effectively dealt with. There are, of course, imperfections—for instance, the special allowance of £45 in respect of wife's earnings is no longer conditional on their being independent of the husband's earnings; and, in a somewhat similar connexion, the wife of a husband who has no residence in this country is not, in general, assessable in respect of remittances from his earnings, though the note on page 27 would lead the reader to assume the contrary. On the whole, however, this little book can be recommended as giving as good value for the price as can be obtained anywhere in this field.

#### NOTES ON BOOKS.

THE thirty-third edition of *Burdett's Hospitals and Charities*<sup>11</sup> has recently been published, and although the range of information has been increased it has been found possible, by the exclusion of all obsolete matter and by condensation and revision, to reduce the size of the volume by over a hundred pages. The military and naval section has been augmented, particulars of hospitals where the Ministry of Pensions has financial liability have been added, the new names of Poor Law infirmaries are given, with a list of the local committees set up by the Voluntary Hospitals Commission appointed by the Ministry of Health. The first 66 pages deal with hospital finance, the classified lists, with the analysis of the expenditure under different heads and the sources of their incomes, being particularly useful. Then follows the detailed directory of hospitals and other charitable institutions, occupying some 800 pages, and including hospitals not only in Britain but in the dominions, colonies,

<sup>9</sup> *Traité de Pathologie Médicale et de Thérapeutique Appliquée*. Published under the direction of L. Sergent, L. Ribadeau-Dumas, and L. Babouneix. Tome xiii, *Reins et Organes Génito-urinaires*. Paris: A. Maloine et Fils, 1923. (Demy 8vo, pp. 831; 61 figures. Fr. 35.)

<sup>10</sup> *Nelson's Income Tax Guide*. By P. Sulley. London, Edinburgh, and New York: T. Nelson and Sons, Ltd., 1923. (Cr. 8vo, pp. 221. 2s. net.)  
<sup>11</sup> *Burdett's Hospitals and Charities, 1922-23*. Founded by Sir H. Burdett, K.C.B., K.C.V.O. Thirty-third year. London: The Scientific Press, Ltd., 1923. (Cr. 8vo, pp. lxxxvi + 875. 17s. 6d. net.)

America, and other foreign countries. It is interesting to note among the many other details that in Australia, although the hospitals appear to be managed by elected committees of subscribers, large grants are made by the Government. In connexion with the American hospitals the size of the medical staffs is noticeable, particularly perhaps in the special hospitals of New York; one of the New York eye, ear and throat hospitals, for instance, with 175 beds, has a staff of thirteen consulting surgeons and two physicians, thirty-four surgeons and eight clinical assistants in the ophthalmic department, thirty-four surgeons and five clinical assistants in the aural department, forty-three surgeons and five clinical assistants in the throat department, and seven house-surgeons—nor is the size of the staff of this hospital unusual as compared with others in that city.

In the preface of his monograph, *Anaesthesia in Children*,<sup>11</sup> Dr. HEWLETT states that "most of the elementary teaching has been omitted. . . . As far as possible simple methods have been described in order to make the book more useful to the general practitioner who is unable to employ complicated apparatus." Yet among the illustrations one finds figured Boyle's gas and oxygen apparatus, the direct vision laryngoscope, Hood's apparatus for infusion anaesthesia, the Davis gag, and the Yankhauser combined pressure and suction outfit; moreover, in several cases the methods for using such apparatus are fairly fully explained in the text. It is, however, unlikely that the average general practitioner will go to the expense of providing such instruments. Though the author can hardly be said to have achieved his object of describing only simple apparatus, there is little fault to be found with his teaching. As is but natural, ethanasesol comes in for a full description at the hands of its pioneer administrator, and various little "gadgets" invented by him are also described. Should a second edition be called for the author will do well to revise the text carefully in order to remove some literary blemishes which have escaped his eye.

Judging from the output in America of handbooks intended for non-medical readers, the lay public seems more open in the New World to personal education on health subjects than in this country. *Personal Hygiene Applied*<sup>12</sup> is a book of this class; in the course of fourteen chapters the author, Dr. J. F. WILLIAMS, discusses the application of the principles of hygiene to the various functions and organs of the body—the muscular and skeletal systems, nutrition, respiration; the circulatory, excretory, and nervous systems; the sexual aspects of life; the mouth, eye, and ear; the prevention of specific disease, and other such matters. The author deals faithfully with Christian Science, osteopathy, and the occult. Here and there in the volume he takes the opportunity to expose "prescription fakes" and misleading advertisements. He discusses the forces of instinct and of intellect in determining human conduct, and urges that the ideal of social responsibility arises out of the nature of life, each individual being a link in the chain of life, and an heir to the inheritance of life, with its responsibility. The book is well fitted to fulfil its purpose.

Dr. WILLIAM WILSON's *Handbook of Aural Surgery for Students and Practitioners*<sup>13</sup> would have been better described as a synopsis of otology, for the work takes that tabulated literary form which is becoming ever more familiar, and the author does not confine himself to the surgical side of his subject. Descriptions of some recent operative methods have been introduced into the text which seem a little out of place, having regard to the scope of the book as expressed in its title. It is hardly likely, for example, that either a student or a practitioner will be called upon to perform an elaborate operation on the labyrinth, whilst the style of the book, though convenient for reference, makes consecutive reading difficult. Where economy of space is of importance in order to cover a wide range of topics this method of writing may be justifiable, and for those who take their reading as a draught of medicine the book can be safely recommended; but anyone who expects to derive pleasure as well as instruction will, we fear, be disappointed. The information and advice given are clear and on the whole orthodox; but the author is at some pains to point out that he considers himself in certain respects in advance of opinions generally accepted, and especially of those likely to be held by examiners. The book should serve as a useful introduction for anyone taking

a course in the subject, though unnecessary stress is laid upon rare conditions and upon elaborate operative procedures seldom required and difficult to perform.

Professor MAX NEUBURGER of Vienna deserves our gratitude for bringing out in facsimile the original edition of Leopold Auenbrugger's *Inventum Novum ex Percussione Thoracis Humani, ut Signo Abstrusos Interni Pectoris Morbos Detegendi*<sup>14</sup> (1761), and also the translations into French by J. N. Corvisart (1808), into English by Sir John Forbes (1824), and into German by S. Ungar (1843). This interesting reproduction is rendered more complete by Professor Neuburger's biography of Auenbrugger, which contains two facsimile letters to his senior contemporary the omniscient Albrecht von Haller of Bern. Of the three portraits in the volume two are of Auenbrugger, that inserted at the beginning of his life being the better; the other portrait is appropriately that of Corvisart. Auenbrugger published the *Inventum Novum* when he was 38 years of age, but it was years in advance of the times and did not receive its due recognition until Corvisart's influence brought its principles into medical practice. Corvisart's translation appeared the year before Auenbrugger's death in 1809. This well printed volume will appeal to the growing number of those interested in medical history.

*Willing's Press Guide*<sup>15</sup> is a useful work of reference containing a list of the newspapers and periodicals published in Britain, with particulars of their date of foundation, politics (if any), date of publication, price, and address; lists are also given of overseas, American, and of the principal newspapers printed in various countries, as well as of Continental newspapers published in the English language. The British periodicals are further divided according to their interests, professions, trades, sciences, and subjects; the London addresses are given of colonial, foreign, and provincial newspapers, and provincial newspapers are also arranged according to the counties and towns where they are published. An interesting couple of pages are devoted to those newspapers and periodicals which date back to the seventeenth and eighteenth centuries: with the exception of the official *Gazettes of London* (founded at London), *the Edinburgh Gazette* (founded at Edinburgh), and *Dublin*, the earliest newspaper to be the *Worcester Postman* (subsequently called *Berrow's Worcester Journal*), which was founded in 1709.

*Small-pox and Vaccination in Barbados*. Dr. JOHN HUTSON, who holds the office of Public Health Inspector for Barbados, has reprinted as a pamphlet three articles he contributed to the local press in exposition and defence of vaccination. Thirty years ago Dr. T. L. Gaskin had taken similar action to counteract prejudice then existing. It appears that recently there had most unfortunately occurred two deaths in one household within two weeks after vaccination, and this naturally caused a revival of antivaccination writings. Dr. Hutson's articles show close and extensive knowledge of the subject, and are written calmly and convincingly. They ought to have much effect with reasonable readers, and should evoke the thanks of all who are interested in the protection of the inhabitants from the scourge of small-pox.

<sup>14</sup> Leopold Auenbrugger's *Inventum Novum*. Facsimile nach der Ersten Ausgabe. Begleitet von der Französischen Übersetzung Corvisart's, der Englischen von Forbes, der Deutschen von Ungar. Herausgegeben und mit einer biographischen Skizze versehen von Dr. Max Neuburger. Wien und Leipzig: Josef Scharf. 1922. (Med. 8vo; 3 portraits, 2 facsimile letters. In boards, £1 1s. 3d.; in half-morocco, £1 5s. 9d.)

<sup>15</sup> *Willing's Press Guide*. Fiftieth year. London: J. Willing, Ltd. 1923. (Demy 8vo, pp. xl + 451. 2s. 6d.)

## MEDICAL AND SURGICAL APPLIANCES.

### A Non-Grip Cover-slip Holder.

DR. M. W. GEFEN has devised a non-grip cover-slip holder for microscopic work. It consists of a stiff wire framework fused into a glass-rod handle. The wire is bent into the shape of two Y's, one above the other, and united at the ends of all three arms of one Y to the corresponding arms of the other. The cover-slip is inserted between the two Y's, where it will remain in position until the instrument is held end downwards, when the cover-slip slides gently out on to the slide, as required in mounting. At the choice of the user, the glass-rod handle may be bent at a right angle, or circularly, so that the holder will not roll, and an upward bend to the wire stem leaves the slip secure and steady. The wire has been chosen to stand the flame well, and will not readily corrode with wet or acids; it is quite pliable, and can be easily bent between the fingers to hold any size of cover-slip. The bent instrument, he considers, presents the following advantages: that its cost is trifling; that there is no grip on any part of the slip, so that breakages are avoided; that play is allowed for expansion in the flame; that the handle is long and made of non-conducting material; that the wire is malleable; and that sterilization by flame is easy. The instrument is made by Messrs. Allen and Hanbury.

<sup>11</sup> *Anaesthesia in Children*. By C. Langton Hewar, M.B., B.S. Lond., M.R.C.S. Eng., L.R.C.P. Lond. London: H. K. Lewis and Co., Ltd. 1923. (Cr. 8vo, pp. viii + 111; 31 figures. 4s. 6d. net.)

<sup>12</sup> *Personal Hygiene Applied*. By J. F. Williams, A.B., M.D., Philadelphia and London: W. B. Saunders Co. 1922. (Post 8vo, pp. 412. 12s. net.)

<sup>13</sup> *A Handbook of Aural Surgery for Students and Practitioners*. By William Wilson, M.D., B.Sc. Manchester: Sherratt and Hughes. 1922. (Cr. 8vo, pp. 336; 100 figures. 15s.)

## British Medical Journal.

SATURDAY, FEBRUARY 10TH, 1923.

### THE TREATMENT OF GASTRIC AND DUODENAL ULCERS.

SYDNEY SMITH is credited with having made the very commonplace remark that "It is wonderful what a different view we take of the same event four-and-twenty hours after it has happened." And these words, commonplace though they are (for they have been uttered by humanity before and since Sydney Smith's time), must have sounded like the epitome of wisdom to those who heard and to those who will read Sir Berkeley Moynihan's address delivered at the Hunterian Society meeting in London on January 29th. The subject of the address was "Some problems of gastric and duodenal ulcers," and in a delightful way the salient points of a much-debated problem were isolated and considered. It is in connexion with the recommended treatment that Sydney Smith's words seem so apposite, for Sir Berkeley advises that, to obtain the best results, chronic gastric ulcer should be dealt with by the operation of partial gastrectomy. Ten years ago what would we have said to this recommendation? Yet to-day it is difficult to see what answer but that of assent can be given to Sir Berkeley's advice.

The address is full of a wide variety of clinical wisdoms. There are none of us who can afford to neglect the advice as to the value of constantly reviewing and examining case results. The successful surgeon must be an optimist, but rose-coloured spectacles should not be included in his gifts. "To see things as they are, to know the truth, and thence to find the right"—in these things the modern surgeon will do well to follow in the footsteps of the Roman sage. As the lecturer very aptly puts it, "To review our own work is a very stern and salutary discipline"; and "From a long array of cases we can glean knowledge that the single case can never disclose. The years certainly teach much that the days never knew." It is difficult to over-estimate the value of such advice, more especially in days such as these, when almost every aspect of our lives is in a constant whirl of change. When those who are responsible for much of our modern surgical and medical literature will act upon this truth less ink will be spilled and more truth will be told.

Ten years of experience in the treatment of gastric and duodenal cases forms the subject matter of the address: it embodies a total of 718 cases, 531 of these being duodenal and 164 gastric ulcers. Only chronic ulcers are included in the category, and a clear line of distinction is drawn between the chronic and the acute types of the lesion. The differentiation is important because the problem which each presents is vitally different; whether viewed from a clinical or an operative standpoint, there is a very clear and evident distinction. As Sir Berkeley points out, it is the chronic ulcer which gives us anxiety, for it is in this variety that we meet with the disastrous complications of haemorrhage, perforation, and malignant degeneration.

The problem of the etiology of chronic gastric and duodenal ulcers remains unsolved; it is assumed that an acute ulcer may form the nidus in which the chronic ulcer eventually develops, but such an answer is insufficient. In this connexion Sir Berkeley makes no mention of the influence of distinctive types of stomach cells upon the

situation and occurrence of the disease, though recent histological work on the "map" method suggests the importance of this influence.

Great interest from the pathological point of view centres round the question of malignant degeneration in the ulcer. There are few who will dispute the possibility of the event, and the instances the lecturer quoted should convince the most sceptical. The recognition of the possibility is of extreme importance, and it naturally forms one of the strongest arguments for surgical ablation of the ulcer. It is refreshing to find that this shrewd observer attaches the greatest importance to the careful interrogation of subjective features. It is well that we should be reminded of this, for the technical nature of many modern methods of investigation is sometimes apt to overshadow the personal subjective factor. An impressive distinction in this connexion is drawn between the individual clinical histories of a gastric and of a duodenal ulcer.

Apart from the clinical history, radiological examination and gastric analyses afford the information upon which the diagnosis is eventually based. The visible evidence of x-ray examination will probably continue to be our most valuable mechanical aid. The demonstration of a "crater" is proof positive, but there are many who will not share Sir Berkeley Moynihan's confidence in the "niche" and the "notch"—the latter especially is open to suspicion, for its interrogation may be read as a localized contraction of the stomach, and it has been demonstrated as a "fractional gastric analysis" has displaced other methods of gastric analysis, but the method has not yet been brought to the pitch where its evidence can be regarded as more than confirmatory. The curves obtained from a fractional gastric analysis may afford suggestive information, but, while a positive result is of value, nothing can be assumed from a negative reading. This is especially manifest in duodenal ulcer—in hyperchlorhydria the curve of "terminal ascent" may only be met with in a small proportion of the cases. The method, as yet in its beginnings, promises, however, to be of increasing value.

A considerable proportion of the address is devoted to a consideration of the curative value of medical treatment. Sir Berkeley Moynihan claims that he is a physician who has been led by force of circumstances to practise surgery, and it seems to us that he has stated the arguments of the relative values of medical and surgical treatment with remarkable fairness—in fact, he has given the former a consideration which should prove a stimulus to the physician. He has demonstrated to his own satisfaction that the chronic gastric ulcer is capable of spontaneous cure, for the healed scar has been apparent *post mortem*, but he asks the physician to supply the explanation and to initiate the successful treatment. Until this distant goal (we had almost said "Utopian," but there is surely nothing chimerical in the possibility) is reached the claim of the surgeon, as expressed by Sir Berkeley Moynihan, is that the ulcer-bearing segment of the stomach should be removed. The pleas which he brings forward are extremely cogent, and it is difficult to raise any strong objection to them; one aspect of the argument for operation, however, demands a passing notice. Sir Berkeley Moynihan claims that the extraordinarily low mortality associated with the operation is one of the strongest arguments in its favour, but it is here that the personal factor bulks so largely. The operation of gastrectomy will always be one of the most serious operations of surgery, and judgement and exquisite surgical technique are demanded if uniformly successful results are to be attained. To an onlooker it may seem that with such an extraordinarily low associated mortality

the operation must be one of simplicity and inherent safety—and so it is in the hands of an expert, but any error of technique or judgement is likely to be followed by disaster. A word of warning on this point might with advantage have been uttered.

There is one last feature connected with gastrectomy which calls for mention. Experimentally the operation has been followed by a curiously large proportion of acute jejunal ulcerations. This is especially so in the dog, where the active acidity of the gastric contents is badly tolerated by the intestinal mucosa. It would be interesting to know whether, when the operation in man is done in the presence of hyperchlorhydria, there is a greater liability to this complication. We observe that the lecturer records its occurrence in several duodenal cases, and this is the explanation which suggests itself. Experimentally a very long interval of time sometimes elapses before the jejunal ulceration manifests itself; have we any reason to fear its development as a late result in gastrectomy? Possibly it is yet too soon to say. "It is wonderful what a different view we take of the same event four-and-twenty hours after it has happened."

### THE INSURANCE MEDICAL SERVICE.

During the past two years there have been suggestions from several quarters that an inquiry should be held, by Royal Commission or otherwise, into the working and effects of the National Insurance Acts. It has not in every case been evident that the motive prompting the suggestion has been a simple wish to discover truth: indeed, it has been accompanied sometimes by the avowed hope that discredit would be brought on the Insurance Service. Nor has the purpose of the inquiry been clearly stated. It might be threefold: into the finances of the Acts, both as to their administrative cost and as to the allocation of the funds to the different benefits provided; into the efficiency of the working of the system within the limits laid down, and the desirability and method of extending those limits; and into the effect of the system upon public health and national well-being. The time may be almost ripe for an inquiry limited to the first of these purposes. Further experience over a number of years under more normal conditions is probably required before any safe conclusions can be drawn as to the third. With regard to the second, more practical results than could be expected from any inquiry may accrue from such Conferences as that which was held last week at the invitation of the Insurance Acts Committee of the Association, and from the work of the standing committee which that Conference set up.

As will be seen from the full report in the SUPPLEMENT, the scope of the Conference was wisely limited: within this scope it should prove helpful. No representatives of the Ministry of Health were present, but all other sections of National Health Insurance workers were adequately represented. Scotland and Wales had spokesmen of marked ability. The atmosphere soon became friendly, though this did not prevent the complaints and criticisms of all sections being quite outspoken. This was as it should be. Some three or four of the speeches from approved society representatives consisted solely of general denunciation of the insurance system or of the character of the medical service given, but such vague declamation evidently did not impress the Conference, and was indeed repudiated by several other members of approved societies. Generally, specific points were dealt with in a practical manner with a view to their nature and importance being appreciated by the other sections of the Conference, and a number of useful suggestions were made for remedying defects or overcoming difficulties. These will be considered and reported upon by the new standing committee.

There are, no doubt, in the aggregate a considerable number of insured persons who have never claimed either the sickness benefit or the medical benefit to which they have become entitled, and it is possible that a large proportion of these would state as their reason that they expected something superior in the treatment they would obtain outside the service. This is a survival of an attitude not uncommon during the early stages of medical benefit, and is not based upon experience. There are also a relatively small number of insurance practitioners who have not shown that thoroughness in their work and consideration for their patients which is expected of them, and in these cases some thousands of insured persons have been affected and may have expressed, as the result of their own experience, an opinion of the service which has no justification when applied to the whole. The Insurance Acts themselves provide the machinery by which imperfections in the attention given to insured persons are constantly brought to public notice, not merely in serious cases but in those which are trivial; and although doubtless many complaints do not become vocal by the use of this machinery, on the other hand all the good steady work of the ordinary practitioner and all the friendly help given and extra services rendered go unrecorded, but are nevertheless an abundant reality in the daily lives of millions. Considerations of this kind were brought out at the Conference, and altogether it did not appear that there was any justification for general charges against the efficiency of the health insurance service within its present limits or that any improper distinction is made between the medical treatment given to insured persons and that given to others. The complaints of some insured persons both as to the administration of sickness benefit and as to the treatment received under medical benefit were seen to be curiously parallel both in their nature and in their explanation; and it is clear that both doctors and approved society officials do well to remember that generalization is dangerous, and that even grievances which appear well founded often receive a satisfactory explanation in the light of fuller knowledge.

Nevertheless, wherever defects are discovered it is to the interest of everybody that they should be removed, and where these defects are due to the real delinquency of any doctor it is certain that such delinquency will not be condoned by the profession, whose standard of judgement will probably be more severe than that of the laity. Most of the defects could be dealt with by the appropriate local action already provided for, and it seems worth while to consider whether an occasional joint meeting of the Insurance Committee and the Panel Committee of an area might not prove useful. Serious fault was found with the standard of medical certification. The importance to approved societies of trustworthy certification is clear, and their demand that they should be able to rely absolutely on the certificates of every medical man is quite incontrovertible. A distinction must be made between the mere technical breach of some certification rule and the signing of an untrue statement; but the latter can never be justified by calling it the former, and is an offence against the honour of the profession which may properly be visited with severe penalties. Insurance practitioners cannot afford to ignore this matter, and will not wish to do so.

The incompleteness of the service is recognized, but its extension—whether to include persons not now included or to embrace additional kinds of treatment and accessories to treatment—is so bound up with finance as to be an exceedingly difficult problem. The Conference made it clear that such an extension as would give greatly increased medical, surgical, dental, and nursing facilities to all insured persons was dear to the hearts of many representatives. The medical profession equally

desires these extensions. To pretend, however, as some have done, that all these things could be provided within the limits of the present Central Practitioners' Fund is quite foolish. In connexion with the reconsideration of the capitation fee at the end of this year, it may be found possible to provide for a reasonable extension of diagnostic facilities; but there is no real hope of completion of the service without serious additional national expenditure, unless a wide view is taken of that co-ordination of health services which the profession has long advocated, and which was referred to at the Conference by Mr. Canter and others. The total amount of money at present expended on National Health Insurance, on the Poor Law medical service, on the school medical service, on maternity and infant welfare centres, and on tuberculosis and venereal diseases schemes, might, if properly used, provide such a completion of the insurance health service for all classes of suitable persons as would, without departing from the present general lines and principles, go far to satisfy the aspirations of those who are working for the national health. Here is the task awaiting a Minister of Health of sufficient knowledge and vision.

#### THE ETIOLOGY OF DISTEMPER.

In the annual report of the Medical Research Council a paragraph is devoted, as was noted in our article on the report published on January 20th (p. 110), to the fact that the Council had made arrangements for an experimental study of distemper in dogs. The etiology of distemper is unknown, but it is clearly an acute specific infectious disease, presenting resemblances to diseases of the same class in man. A certain resemblance to measles has been noted by many medical dog owners, but it seems probable that it is more like influenza, and may even possibly be due to the same infective agent, though this is perhaps not probable. The Medical Research Council has for some years been encouraging researches into influenza, and Dr. Mervyn Gordon communicated his results to the Section of Microbiology of the Annual Meeting of the British Medical Association in Glasgow last July. His paper was published in our issue of August 19th (p. 299), and was illustrated by a special plate showing a microphotograph of a filter-passing organism in culture. Dr. Gordon saw reason for believing that influenza, and also common cold, is due to a filtrable virus. In this he confirmed results obtained in the Army Medical Service during the war, and more recently at the Rockefeller Institute. It seems probable that the infective agent of distemper in dogs is also a filtrable virus, and that, as in influenza, the severity of the resulting disease depends largely upon secondary infections, facilitated by the primary infection. There is ground for the hope that the study of distemper under strict experimental conditions may throw important light upon analogous problems of human disease; the direct results may, it is hoped, disclose the possibility of relieving or preventing the malady in dogs, and of reducing the great economic loss which it causes to this country. The Council stated that it had already received assurances that independent financial support would be forthcoming to meet the special cost of this investigation. An appeal was last week issued, signed by the Dukes of Beaufort and Portland, and Sir Theodore Cook, editor of the *Field*, for contributions to a Distemper Fund, which will be administered by a council consisting of masters of foxhounds, dog owners, and a number of biologists, and members of the medical and veterinary professions, including Sir Ray Lankester, Sir David Bruce, Sir William Leishman, Sir Walter Fletcher, Sir Humphry Rolleston, Professor C. J. Martin, Mr. Frederick Hobday, F.R.C.V.S., and Dr. H. Hammond Smith. The Council of the *Field* Distemper Fund at its first meeting assigned the direction of the research work to a Technical Scientific Committee, to be

appointed by the Medical Research Council; this committee, of which Sir William Leishman will be chairman, will be responsible for the practical conduct of the investigation.

#### INFLUENZA AND THE LAY PRESS.

THE publication of our note last week calling attention to the recent observations of Sir Spencer Lister with regard to the presence of a filter-passing organism in influenza has been followed by numerous announcements in the lay press emanating from America to the effect that the influenza germ has been isolated there, at the Rockefeller Institute for Medical Research, by Olitsky and Gates. This statement, without further details, does not advance matters. The valuable work of the Rockefeller observers mentioned was referred to in our note, and in connexion with the actual discovery of a filter-passing organism in the acute stage of influenza the still earlier work of Graeme Gibson and others must also receive due appreciation. It is well, however, to sound a note of caution. Although evidence in support of the view that influenza is due primarily to a filter-passing organism is fast accumulating, it has not yet been fully established that "influenza vera" is due to an organism of this group, and in the later stages other organisms undoubtedly play an important part. At present our knowledge of filter passers is at a very early stage. In addition to diseases such as poliomyelitis, variola, and measles, it would seem likely, from the observations of Foster in America and Embleton in this country, that one type of the common cold is due to an organism of this group. The exact relation between this organism of colds and the filter passer found in influenza has still to be determined. The work of Dr. Mervyn Gordon of St. Bartholomew's Hospital, to which reference is made above, is being actively pursued, but the technical difficulties attending such inquiries are great.

#### THE EXHIBITION OF JENNER RELICS.

LAST week we noticed (p. 205) the Jenner Relics from the Wellcome Historical Museum, 54A, Wigmore Street, exhibited at the house of the Royal Society of Medicine on the occasion of the Jenner centenary lecture by Sir William Hale-White. The whole collection is now on view in the hall of the museum (54A, Wigmore Street), and we are glad to learn that the curator, Mr. Thompson, is on the point of issuing, for the convenience of visitors and others, a condensed catalogue of the Jenner exhibits, which are numerous and varied. The bronze statue by Monte Verde, of which there is a marble replica in Genoa, occupies a prominent place, and is one of the permanent possessions of the museum. It has been sometimes described as "Jenner vaccinating his own son," but that is wrong. In 1789, seven years before his first vaccination, Jenner inoculated his son with a mild strain of small-pox, denominated swine-pox, at that time prevalent. Nor does it represent James Phipps, his first vaccinee, who was several years older than the boy figured on Jenner's knee in the bronze group. The artist has simply depicted Jenner in the act of vaccination. Among the pictures shown is a water-colour sketch of the college in which James Phipps lived. Jenner inoculating his own son is the subject of a painting also contained in the exhibition, and there are about fifteen oil paintings of Jenner. Probably they were not all taken from life, as the differences between them cannot wholly be accounted for by the age of the subject. There is a portrait in oil of Mrs. Jenner (by Sir Peter Lely), and of their daughter. The collection includes a medallion profile of Jenner, modelled in wax from life in 1803, and a very good pencil profile evidently intended for a medal, but never produced as such, though it appears as an engraving. The striking of medals to commemorate notable events has been much commoner in other countries than in England. A case in the exhibition contains an astonishing number of vaccination medals from France, Italy, Belgium, and Germany. One English medal, however, is of particular significance. It is quite small,

a replica of one in the British Museum, which is perhaps the only example in existence of a medal struck to commemorate the recovery of Queen Elizabeth from small-pox. The head of the queen is shown in profile on the medal. The Continental medals were probably used for propaganda of vaccination. Some of the framed diplomas and addresses include notable signatures, as, for example, one from Edinburgh with the names of William Cullen, Benjamin Bell, George Bell, Andrew Duncan, and John Thomson. The diploma of the Physical Society has more than a hundred signatures. The valuable gold enamelled box in which the freedom of the City of London was presented in 1803 is one of the exhibits. The Royal College of Physicians has lent for the exhibition Jenner's favourite armchair, in which he was sitting when he died. There is also a memorial gold ring which he had made on the death of Mrs. Jenner. Among the many manuscripts exhibited is a letter which Jenner wrote immediately after the momentous vote of the House of Commons awarding him £20,000 in recognition of the value of vaccination, in addition to the previous vote of £10,000. The fact that Jenner was awarded these sums is one of the standing grievances of the anti-vaccinator of the present day. There is also the manuscript of a jocular couplet which he sent along with two ducks to a convalescent patient—

"A regular physician she no longer lacks,  
So I send you, dear Madam, a couple of quacks."

An important letter, dated September 7th, 1800, to Dr. Davids of Rotterdam, who was largely responsible for the introduction of vaccination into Holland, contains Jenner's constantly reiterated advice about the importance of collecting lymph at an early stage in the progress of the vaccine vesicle. These are mere samples of the contents of the exhibition, which no doubt contains the best Jennerian collection ever brought together in one place, and is of the utmost interest to the whole medical profession. The collection of books was referred to in our previous notice.

#### VENEREAL DISEASE IN NEW ZEALAND.

We have received a copy of the report of the Committee appointed last year by the Minister of Health in New Zealand to inquire into the prevalence of venereal disease in that country, and to advise as to the best means of combating it. The results are of special interest, since they appear at a time when in our own country a similar committee is at work. Although the conditions in New Zealand differ from those at home, the problem is essentially the same, and many of the Committee's recommendations, although possibly not all, should be applicable here. Perhaps the most important part of the report is that which deals with legislation; the Committee recommends the adoption of what is known as the system of conditional notification embodied in the Western Australia Act. Under this plan cases are notified by the doctor by number or symbol only, and it is only when a patient refuses to do what is necessary for his own safety and for the safety of others that the name is sent to the Health Department in order that appropriate steps may be taken in the interests of public health. The obligation to notify is, in this particular scheme of notification, placed on the medical practitioner, who is entitled to a fee for his services. To supplement notification, provision is made for the enforcement of treatment, the Director of General Health being empowered to demand of any person who he has reason to believe is suffering from venereal disease a certificate showing that he is receiving treatment or is cured. Should the said person not comply with these requests, the Director-General of Health may obtain a warrant from a magistrate ordering him to undergo examination. In the event of his being found to be suffering from venereal disease he may be detained in hospital or other approved place until cured, or at any rate until rendered non-infectious. In addition to this the Committee recommends "the adoption of a provision of the Queensland Act, which makes venereal disease a ground for annulling a

marriage contracted whilst one party is suffering from such a disease in an infectious stage, provided that the other party was not informed of the fact prior to marriage. Also that it should be the duty of a medical practitioner attending a case of venereal disease, if he has reason to believe that the patient intends to marry, to warn him or her against doing so, and that if he or she persists it should be the duty of the doctor to notify the case by name to the Director-General of Health, whose duty it should be to inform the other party or parents or guardians of such other party. Such communications made in good faith either by the doctor or the Director-General of Health should be absolutely privileged." It will be seen, therefore, that the New Zealand Committee is prepared to go farther in legislation than most of those who have considered these questions in England would dare to recommend in the case of the mother country. For the proper working of such an Act the co-operation of medical practitioners would be absolutely essential, since the whole onus of notification rests upon their shoulders. We do not know whether the recommendation of the New Zealand Committee will receive the support of medical men in that country, and it would be of interest to have a statement of their collective opinion on the legislative measures outlined above. The medical profession is, as a whole, conservative in the views it holds on the subject of medical legislation, and rightly regards with suspicion any measures tending to disturb the confidence that exists between doctor and patient. Of one thing there can be no doubt, and that is that, should the recommendations of the Venereal Diseases Committee of New Zealand be adopted, their success will almost entirely depend on the support they receive from the medical profession. In any case, whether these legislative measures become law or not, the report of the Committee cannot fail to be of interest to all those who are dealing with similar problems at home.

#### THE PASTEUR CENTENARY.

The rooms of the Royal Society at Burlington House were crowded on the afternoon of February 2nd, when Dr. Pasteur Vallery-Radot delivered a lecture on Pasteur, under the auspices of the Alliance Française, with Sir Charles Sherrington, G.B.E., M.D., President of the Royal Society, in the chair. The Alliance Française has arranged for twelve addresses (of which this was the first) to be given by Dr. Vallery-Radot at Cardiff, Manchester, Newcastle, Liverpool, Reading, Bradford, Portsmouth, Bexhill, Leicester, and Wolverhampton. Sir Charles Sherrington, in introducing the lecturer, said that he was a grandson of the great scientist, was himself a distinguished pathologist and physician, and had in preparation a collected and annotated edition of the works of his illustrious grandfather. Dr. Pasteur Vallery-Radot, who spoke in French, said that none of the homage that was being paid to Pasteur on the centenary of his birth would have been dearer to him than that of England, because it was the land of Jenner and Lister, and because here he had found some of his warmest partisans and greatest friends. Before the days of Pasteur medicine knew nothing of the cause of virulent illnesses, surgeons were afraid to operate, infection was the great fear of maternity hospitals, industries based on fermentation were powerless, and herds were dying fast. In forty years, however, the genius of Pasteur had changed all that. He transformed microbes from an instrument of death into an instrument of preservation. The work of Pasteur was by its logical linking and its incalculable consequences one of the most wonderful products of the genius of man. He had an extraordinary imagination, but he tempered it by the most strict experimentation. If he had a great mind Pasteur also had a great heart. Modesty was his great characteristic, and his work and his home life were closely linked, because Madame Pasteur was his constant help. He bound together love of his country with love of humanity. His ideal was to see humanity led to peace by the aid of science. In the evening the Alliance Française gave a dinner to Dr. Vallery-Radot.

at the Vintners' Hall, Upper Thames Street, generously lent by the Company. His Excellency the French Ambassador, le Comte de Saint-Aulaire, presided over a company of one hundred, including Sir Arthur Griffith-Boscawen (Minister of Health), Sir Charles Sherrington (President of the Royal Society), Sir Humphry Rolleston (President of the Royal College of Physicians), Sir Anthony Bowlby (President of the Royal College of Surgeons), Sir William Hale-White (President of the Royal Society of Medicine), Mr. A. Chaston Chapman, F.R.S. (President of the Institute of Chemistry), Mr. H. D. Truscott (Master of the Vintners' Company), and Mr. André L. Simon (Président de la Fédération des Comités d'Alliance Française), and many representatives of the brewing and wine interests. The health of Dr. Pasteur Valléry-Radot was proposed by Mr. Cecil Lubbock (chairman of the London Brewers' Council), who, speaking in fluent French, referred to an interesting relic of Pasteur's visit to England in 1871 which had been exhibited before dinner; it was the microscope used by him when working in this country at Whitbread's brewery. Sir Anthony Bowlby paid a high tribute to Louis Pasteur's influence in originating friendly relations between French and British surgeons in the sixties, which bore fruit in the *entente médicale* during the war under Professor Tuffier; he read a letter from Lister to Pasteur acknowledging his debt to the latter's researches. As an experimenter, pathologist, and physician, and by his war service, their guest was a worthy descendant of Pasteur. In his reply Dr. Valléry-Radot gracefully referred to Edward Jenner's work, to the sanitary service of the British army in France during the war, and to Sir Charles Sherrington's world-wide physiological repute. The French Ambassador, in very happy terms, proposed the toast of "The Vintners Company"; and the Minister of Health, as the representative of the British Government, gave the chairman's health, and insisted that the progress of civilization depended on the close friendship of France and Great Britain.

#### INFECTIOUS DISEASE IN SCHOOLS.

WHEN the Medical Officers of Schools Association was founded in 1884 it issued a *Code* of rules for the prevention of infectious and contagious diseases in schools, drawn up by the medical officers of the principal public schools in the country. It was compiled with such great care that it speedily became authoritative, and has deservedly maintained that position ever since. The eighth edition of the *Code*,<sup>1</sup> just issued, bears evidence of the most careful revision, so that it may be considered to express present-day views. The text published at the beginning of the present century advised that a scarlet fever patient might return to school six weeks after the beginning of the illness, and then only if there was no desquamation or sore throat. The rule as it stands in the latest *Code* indicates the changed view which now prevails as to return to school after an attack of scarlet fever: "In not less than four weeks from the date of the appearance of the rash, provided convalescence is completed, and there is no sore throat, discharge from the ear or nose, suppurating or recently enlarged glands, or eczematous patches." As regards diphtheria, the earlier rule advised three weeks' absence from school and return only if convalescence is complete and no sore throat nor albuminuria or discharges remain. We are now able to call to our aid bacteriology in deciding upon freedom from infection in this disease, so that the present rule advises return to school after an absence of at least four weeks, provided that convalescence is completed, that there is no longer any sore throat or any abnormal discharge from the throat, nose, ears, or eyes, no cutaneous pustulation and no albuminuria, and that at least three successive bacteriological examinations of the pharyngeal and nasal mucus for the specific bacillus have given consistent negative results, each examination having been made not less than three hours after the discontinuance of local antiseptic applications. In an appendix to the *Code* practical advice is given on the

methods of disinfection which should be employed after there has been a case of infectious disease in a school. There are also set out forms of certificates which may be used in connexion with the first admission of pupils and with their return to school after holidays. These ought to be of great service to head masters, for it is notoriously extremely difficult to draw up a certificate in terms which precisely express its intention.

#### PHYSICALLY DEFECTIVE CHILDREN.

THE Survey of Physically Defective Children, lately issued by the London County Council,<sup>1</sup> is a valuable and interesting document. It consists of two parts: the first is a criticism on Mr. R. C. Elmslie's report by the school medical officer and medical officer of health for London, Sir W. H. Hamer, and the second is Mr. Elmslie's report, which itself is a criticism of the work of the Council among physically defective children since the last reports in 1907 and 1912. The number of children examined in the schools for the physically defective was 2,294, but it is noticeable that no fewer than 597 cases were not examined on account of absence from one cause or another. The figures show a noteworthy decrease in the number of tuberculosis cases and an equally striking increase in the number of cases of infantile paralysis, which latter disease (as Mr. Elmslie points out) has become the chief cause of crippling among the children under the care of the Council, whereas in 1912 tuberculosis predominated. This change is attributable to various causes, chief among which is probably the improvement in methods of treating tubercle, although it is not improbable that there has been some increase in the prevalence of anterior poliomyelitis. The deformities due to tuberculous disease of the spine seem to be less severe than they were in 1907, and the same may be said of the hip, but the results of treatment of disease of the knee are little improved. The out-patient treatment does not and cannot yield the best results in these cases, which should all be treated as in-patients of special hospitals in the country such as those of Carshalton and Alton. Mr. Elmslie's protest against excision of the knee in children is amply justified by experience. It is to be hoped that improvements in hygiene will cause a continuous decrease in the prevalence of tubercle, but meanwhile there is a crying need for more accommodation and for up-to-date treatment. The public treatment of children who have suffered from infantile paralysis presents a very difficult problem. Despite improved surgical procedures, some of which aim at stabilization of joints, a great many of these cases require permanent instrumental support. Mr. Elmslie states that as many as 50 per cent. of the children with infantile paralysis examined by him in the East End of London were without instruments because those supplied were broken. He suggests that provision should be made for the systematic and continuous treatment of anterior poliomyelitis in its earliest stages and of its resulting deformities in a special institution, or section of an institution, in close relationship with the out-patient departments of special and general hospitals. This country has hitherto been spared any great epidemic of the disease, such as Sweden and parts of the United States experienced in recent years, but we do not know to what circumstances we owe our comparative immunity, nor can we be sure that we shall continue to enjoy it. Other kinds of paralysis do not furnish many cases. Spastic paralysis would probably figure more largely were not many cases so mentally deficient as not to be eligible for physically defective schools. Among congenital deformities were more cases of dislocation of the hip than of club-foot. Both these conditions are often cured before the patient reaches school age, and therefore they do not attend the special schools. Rickets plays a very small part in crippling London children, and would play less were parents more willing to allow operative treatment. Of the amputations, rather more than half were performed on account of accidents and rather less than half for disease.

<sup>1</sup> A *Code of Rules for the Prevention of Infectious and Contagious Diseases in Schools*. Issued by the Medical Officers of Schools Association. Eighth edition. London: J. and A. Churchill. 1923. (Demy 8vo, pp. 48. 2s. 6d. net.)

<sup>1</sup> London: P. S. King and Son. 1923. (Folio, pp. 10. Price 2s.)

Some of the latter were probably done on account of severe infantile paralysis, but no details are given on this point. Mr. Elmslie is no doubt right in saying that artificial arms are useless to children of this class. In a general criticism of the medical organization of the physically defective schools he puts in a strong plea for better organization and co-operation with the various other agencies for the treatment of cripples, and urges that the services of those physicians and surgeons who are engaged in orthopaedic work should be utilized to a greater extent. He is doubtless right in thinking that the physically defective school is not a suitable place for actual treatment, which should be carried out at special clinics and in the out-patient departments of special hospitals or in the orthopaedic departments of general hospitals. The table of hospital attendances shows how few of the cases are cared for at those hospitals which have not an orthopaedic surgeon on the staff. When such institutions have established adequate departments the treatment of London's cripples will be more thorough and general. In his covering report Sir William Hamer sets forth the difficulties which have hitherto prevented the Council from filling up some of the gaps in organization to which Mr. Elmslie refers; one of the chief of these lies in the competing claims of surgical and educational requirements. While the report forms a most valuable survey of London cripples of school age, it cannot pretend to give any account of the proportion of cripples of all ages to the general population and only a partial estimate of the percentages of the various maladies and accidents which are the immediate causes of deformity. A census of cripples, not only in London but throughout the country, is still wanting, and any complete plan for meeting their needs cannot be formulated until we possess fuller knowledge of the magnitude of the problem.

#### THE NEW ELEMENT.

THE fundamental laws of  $x$ -ray emission were established by the young British physicist Henry Moseley, whose death was one of the greatest losses of the war. The laws he formulated made it possible to calculate the wave-length of the  $x$ -ray spectral lines for any element in the periodic table, if those of the elements in its neighbourhood are known. A very small proportion of a definite element in any chemical substance suffices to give a good  $x$ -ray spectrum of that element. Moseley was able in this way to arrange the elements in a series, in which each element had an atomic number. The first element in the series is hydrogen, 1, and there is much evidence to establish the proposition that the total number of elements is 92, the last being uranium. When Moseley was working a good many numbers were unfilled; since then several have been found, but among those hitherto unrecognized was the element with the atomic number 72. Dauvillier reported to the Paris Académie des Sciences on May 22nd, 1922, that he had detected by means of  $x$ -ray spectroscopy the element 72 in a mixture of rare-earth metals; it was provisionally identified with a rare-earth element suspected by Urbain, to which he had given the name "celtium." There were, however, certain theoretical reasons for doubting this identification; it was held to be unlikely that the element 72 could be a rare earth; it was thought probable that it must be a homologue of zirconium, a metal whose affinities are with titanium, cerium, and thorium; its existence, suspected by Klaproth in 1789, was established by Berzelius. Two Danish chemists, D. Coster and G. Hevesy, working in the University Institute of Theoretical Physics in Copenhagen, announced recently in *Nature* that they had identified the presence of element 72 by spectroscopic examination of extracts of zirconium minerals. In one such mineral from Norway the new lines were so intense that Coster and Hevesy estimated that the quantity of 72 in it amounts to at least 1 per cent. As the discovery was made at Copenhagen, the Latin name of which is *Hafnia*, they propose to call the new element "hafnium." At the meeting of the Chemical Society on February 1st Dr. Alexander Scott, F.R.S., director of scientific

researches at the British Museum, whose work on atomic and molecular weights is well known, was able to report that he had isolated the oxide of the new metal from a certain black sand obtained from New Zealand. He had received samples of the sand in 1913, when he extracted from it a cream-coloured material, consisting of magnetic oxide of iron, and titanium dioxide in the proportion of 3 to 1. In the titanium dioxide he had found small quantities of a highly refractory residue. These residues were collected, but their further examination was postponed. The compounds made by the metal in the residue with potassium and fluorine resembled those of titanium and zirconium, and Dr. Scott was stimulated by the discovery by Coster and Hevesy to determine the atomic weight; he found it to be approximately 180; the chemical characters fitted in with the suggestion, arising out of the results of the  $x$ -ray examination, that the substance was an oxide of element 72. Dr. Scott did not apply  $x$ -ray spectroscopy to this oxide, preferring to offer samples to Coster and Hevesy in order that they might be the first to make the examination.

#### THE OPHTHALMOLOGICAL SOCIETY'S CONGRESS.

THE annual congress of the Ophthalmological Society of the United Kingdom will be held at the house of the Royal Society of Medicine on the last three days of the last week of April. On April 26th the president, Dr. A. Maitland Ramsay, will deliver an opening address at 10 a.m., and at 5 p.m. Dr. George E. De Schweinitz (President of the American Medical Association) will give the Bowman lecture. He has taken as his subject certain ocular aspects of pituitary body disorders, mainly exclusive of the usual central and peripheral hemiopic field defects. On the afternoon of the same day a discussion on the disorders of the blood and their ophthalmological manifestations will be opened by Sir Humphry Rolleston, Sir Frederick Andrewes, F.R.S., and Dr. W. C. Souter. On Friday there will be a discussion on the diagnostic significance of proptosis, to be opened by Mr. Wilfred Trotter, Mr. Herbert Fisher, and Dr. Angus MacGillivray. In the afternoon a visit will be paid to the London Hospital, and here a clinical meeting will be held. In the evening demonstrations will be given by members. Persons desirous of reading papers, showing cases, or taking part in the discussions, are requested to communicate with Mr. R. Foster Moore, 91, Harley Street, W.1, one of the honorary secretaries. "All communications must be typewritten."

We are informed that an appeal is about to be made to the public to provide funds for M. Spahlinger to continue his experiments on the production of an antitoxic serum for use in the treatment of tuberculosis, and of a vaccine for early or convalescing cases. Inquiries into the nature and results of M. Spahlinger's methods have been made both by the Red Cross Society and by the Ministry of Health. The reports have not been published, but we gather that the methods were looked upon as interesting, and the results, though hitherto on a very small scale, as encouraging. We are informed that M. Spahlinger is at the end of his financial resources, and that his laboratory and experimental farm at Carouge, near Geneva, may in consequence be closed. We are of opinion that M. Spahlinger should publish a clear account of his theories, with an outline of the methods he has devised for carrying them out.

We announced some time ago that Professor E. H. Starling had been appointed by the Royal Society to the Foulerton Research Professorship. It is now announced that under the same trust Dr. H. W. C. Vines has been appointed a Foulerton Research Student; he is a Fellow of Christ's College, Cambridge, and clinical pathologist to Addenbrooke's Hospital. He is known to our readers especially for his researches on the physiology and therapeutics of calcium.

# NINETY-FIRST ANNUAL MEETING of the British Medical Association, PORTSMOUTH, 1923.

## AN OUTLINE OF PORTSMOUTH HISTORY.

### PORT, DOCK, AND HARBOUR.\*

H.M.S. Victory at her old moorings.

On return to the Port and Docks. When a king wished to cross to Normandy he either used one of his own ships, or employed one belonging to the fleet of the Cinque Ports. If he had a big expedition on hand he had the further right to arrest—that is, commandeer—all the shipping of the country. John, when he lost his Norman province, was the first to exercise this prerogative. Portsmouth and Southampton were no longer opposite a friendly coast, no longer were they the connecting links between two portions of the kingdom. They were now the collecting centres for armies and fleets that tried to win back Normandy. Consequently John was much in Hampshire, and the castle at Porchester, then furnished as a royal residence, was his halting place. From here he used to superintend the preparations of his futile expeditions to France, and this perhaps has given rise to his claim to the title of Founder of the Royal Navy. He was compelled to give some attention to the collecting and manning of his fleets, and for this purpose created the post now occupied by the First Lord of the Admiralty. The first "Keeper of the King's Ships" or "The Keeper of the Sea Ports" was the Archdeacon of Taunton, William de Wrotham. His duties at Portsmouth were arduous.

"He had to carry out the King's orders respecting ships and goods coming into the port; he had to see that the bailiffs of the town did their work properly in supervising the arrival of wine, corn, pork, figs, almonds, rice, cloth, sails, anchors and ships' stores; he had to see that the armour, the engines for throwing stones, and the hurdles used in transporting horses were all in readiness."

More important to Portsmouth than the collecting of fleets was the formation of a kind of dock and dockyard. King John wrote a letter to the Sheriff of Southampton on May 20th, 1212. Translated by Mr. Sparks it reads:

"We order you without delay to cause our docks at Portsmouth to be enclosed with a good and strong wall . . . for the preservation of our ships and galleys. You are also to cause pent houses to be made to these walls, in which all our ships' tackle may be safely kept. Be as quick as you can that the work may be completed this summer. . . . When we know the cost you shall be paid."

\* Concluded from p. 73, January 15th, 1923. An introductory article on Portsmouth and Southsea appeared in the BRITISH MEDICAL JOURNAL of December 9th, 1922, p. 1137.

At this time there was a mill and a pond where the Old Gun Wharf now stands. This was near the opening of a creek that ran from the harbour along what is now Park Road towards the present Town Hall Square. It was in this creek John kept his ships and built his docks. An old book of this date defines a dock as "any place or creek where we may cast in a ship out of the tide way into the ooze, and then when a ship hath made herself a place to lie in, we say the ship hath docked herself." The King's ships were run up the creek on full tide and dragged as far ashore as possible. At low tide they were surrounded with timbers and brushwood mixed with clay, and "a good strong wall" thrown across the mouth of the creek along the shore.

This began the docks, but no ships were built for years to come, although shipwrights were imported from the Cinque Ports to repair ships and galleys. So with these docks we come upon the nucleus which since has gathered round it all that goes to make Portsmouth the foremost naval station of the world. From the harbour grows the dock, from the dock grows the town.

Henry III, like his father, was a frequent visitor, and on one occasion held a great council here. The townsmen naturally took advantage of these visits, and on several occasions got their charters renewed. In 1256 one was granted which gave "our good men of Portsmouth the right to have a Merchant Guild."

For the next hundred years and more there were wars and rumours of wars, and during that time the town suffered much from attacks by pirates, Frenchmen and others. Once it was burned by the barons of the Cinque Ports and twice by the French fleets. In 1445 Margaret of Anjou landed here and was married at Titchfield by Bishop Ayscough to Henry VI. In 1450, during a mutiny amongst the sailors owing to the absence of pay, Bishop Moleyns was slain whilst trying to pacify the mob. The severest penalty of the Church was meted out to Portsmouth—the Great Excommunication. The act of expiation was not performed till fifty-eight years later, and then it was done efficiently and thoroughly.

Portsmouth as a naval base began to revive in the reign of Henry VIII. Southampton was the centre of a large Venetian trade, and so, being commercially prosperous, was not likely to compete with Portsmouth for naval honours. Henry VII began by building the square tower at the end of High

INTERIOR OF ST. THOMAS'S CHURCH, LOOKING EAST.

Street, and the round towers on either side the mouth of the harbour were rebuilt in stone. On June 14th, 1495, a new dock was commenced, the first of its kind in Europe. Sir Reginald Bray was the architect. First the body of the dock was prepared and the sides timbered, then the more difficult task of making and fixing two gates had to be overcome. One gate was in the outer transverse wall in a gap next the long side wall—say the right; the other gate was in a

parallel wall a little way within the dock, but with the gateway between the parallel wall and the left side—that is, the gates were diagonally opposite each other. The ship was manoeuvred round the gates into the basin, the gates shut, and the space between the outer and transverse walls filled in with stones and clay, and, lastly, the water was pumped from the dock. As a result of Mr. Sparks's researches we find that this dock cost £193 Os. 6½d. to build, that the greatest number of men employed on it was 60, and that it took forty-six weeks to construct. The first ship to enter this dock was the *Sovereign*. The making of the dock necessitated the building of forges, workshops, and storehouses, and thus a regular dockyard was established. Mr. Sparks says that the earliest record of a warship being built here was the construction in this dock of a small vessel called the *Sweepstake*, and that she cost exactly £120 3s. 2d. to build!

Henry VIII was fond of the sea and took an interest in naval matters. He added eighty-five ships to the fleet, and is justly regarded as the "Founder of the Royal Navy." For that navy Portsmouth was the chief and only centre for the first half of the sixteenth century. European states were building fleets, and the discovery of the New World caused a greater interest in shipbuilding and larger and larger ships were constructed. The life of the seamen was terrible on the Royal ships—they were overcrowded, the food, poor in quality, consisting of salt meat, fish, biscuit, cheese, and beer, the beer often stored in old oil and fish barrels, and severe penalties were meted out to those who grumbled. Lord Howard reported that out of a crew of 500 on the *Elizabeth* 200 died in a month—he made fires on the ship "of sweet broom" and obtained fresh men, but they died more quickly than the others. Beer and biscuits were wanted in quantities greater than Portsmouth and Southampton could supply. To obviate

some of the trouble five Royal brew-houses were set up in Portsmouth in 1513. Three of them were in "Four-House Green," and remained till the time of Charles II. The fourth house was in St. Thomas Street, and here biscuit making went on as well as brewing. Gosport, on the opposite side of the harbour mouth, no doubt helped to supply some of the biscuit; in late years, at any rate, Gosport became the centre for supplying the navy with biscuit.

Henry VIII held the first royal review of the navy at Spithead. Holinshed tells us "the King having a desire to see his navy together, rode to Portsmouth 1 Aug 1512." This review had one point at least in common with the modern ones—namely, "The King gave a banquet to his Captains before they set out." Previously to the reign of Henry VIII the King's representative had been styled "Constable of the King's Castle at Porchester and town of Portsmouth." Early in Henry VIII's reign the town was looked upon as a garrison town and a governor in command was appointed. Many additional fortifications were built in and about the town, and later in the reign Southsea Castle was built. In 1544 Sir Anthony Knyvet, who was in charge of the work, reported "that the first floor of the square tower within the great fortress is laid." Next year it had to stand a practical test of its utility—a French fleet appeared off the Wight. The English went out to meet them in St. Helen's Bay, but, as there was not sufficient room to manoeuvre the sailing ships, our ships returned to harbour and were protected by the fortresses along the shore. The French, unable to entice the English from the harbour, retired. During the attack, whilst the King was at Southsea Castle, one of the ships, the *Mary Rose*, 500 tons, 400 men, heeled over and

sank. One result of this action was the creation of a Navy Board, which made a fixed naval policy possible. About this time a great iron chain was laid down and drawn across the mouth of the harbour between the Round Tower on this side and a similar tower on the Gosport side.

Elizabeth, the "Lady of the Seas," whose navy defeated the mighty Armada of Spain, and won dominion of the seas, did not support Portsmouth as a dockyard town. She removed most of the naval work to Deptford and other Thames yards. Portsmouth continued neglected till the seventeenth century. In 1623 the famous dry dock built in 1496 was filled in.

The revival of Portsmouth's fortunes was largely due to the Duke of Buckingham, a favourite of James I. Buckingham was appointed Lord High Admiral in 1617. He appointed a commission to overhaul the navy. Portsmouth was again made the rendezvous of the fleets. Buckingham and the young Prince Charles set off on a "philandering" expedition to Madrid in 1623, one of their objects being to arrange a marriage between the Prince and the Infanta of Spain. Their scheme failed, and ships were got ready to fetch the pair back. The King came down in August to view the fleet before it sailed. In October the Prince and Duke returned, and shortly afterwards a bust of Charles was

set in a niche in the north wall of the Square Tower in St. Thomas Street, and under it the words can still be read: "After his travels through all France into Spain, and having passed very many dangers, both by sea and land, he arrived here on the 5th day of October, 1623." In August, 1628, Buckingham was assassinated in his house, now No. 10 High Street, by a disappointed soldier, John Felton.

At the commencement of the civil war Portsmouth was wanted by both parties. Colonel Goring, the Governor, made the Mayor and

PORTSMOUTH FROM GOSPORT HARD, SHOWING FLOATING BRIDGE AND PART OF HARBOUR.

Aldermen swear allegiance to the King, and he sent a small body of troops to hold Portsbridge, then, as now, the only way on to the island by land. Parliament sent ships to blockade the harbour and troops to Portsdown Hill. Portsbridge was soon overpowered, and further fighting took place on the north wall of the town. Some of Goring's men deserted, shots were fired into the town from Gosport, Southsea Castle was scaled and seized. Goring capitulated and was banished to Holland, and Portsmouth remained in the hands of the Parliamentarians till the end of the war.

The Commonwealth was a period of great activity at Portsmouth. Henceforth the growth of the town was to be measured by the growth of the fleet. A number of special committees were appointed to manage the navy, each with separate work to do. The value of Portsmouth as a naval base was soon recognized. Five new vessels were built. The first built was christened *Portsmouth*, and during her career put up a good record. Much repairing was done in the yard, new storehouses and shops erected, and a new dry dock built. During the Dutch wars there were many wounded men in Portsmouth. There were no hospitals, and the men, crippled by wounds and disease, were placed in stuffy public houses, and many such houses had sprung into existence. Porchester Castle received many sufferers, as it was no longer used as a residence. Elizabeth Atkin—a forerunner of Florence Nightingale—did noble work amongst the unfortunate soldiers and sailors. Amongst the wounded here was the famous Robert Blake, a native of Bridgwater, who eventually became admiral and general at sea.

The reigns of Charles II and James II were good times for Portsmouth. Samuel Pepys was during the Restoration a

frequent visitor here, and there are many entries in his diary about his visits. In 1662 on one of his visits he was made a burgess, and the honour cost him "a piece of gold to the Town Clerk, ten shillings to the Bailiffs, and spent five shillings." During the same visit "by coach to the yard and then on board the *Swallow* in the dock, where our Navy Chaplain preached a sad sermon, full of nonsense and false latin."

New docks and slip and new warehouses were built and the gunwharf commenced, and complete remodelling of the fortifications took place in the early years of Charles II; and twenty-six new vessels were built. One was christened the *Charles Royal*, and was inspected by the King, who was "infinitely pleased with the sight."

On May 14th, 1662, Catherine of Braganza landed at Portsmouth and was housed in the Domus Dei in rooms "all rarely furnished." She was met by the Duke of York, but not married to him till a week later, when the King arrived. The marriage ceremony was privately celebrated in the Queen's apartment. The marriage was duly registered at St. Thomas's Church and a copy of the entry can be seen in the porch.

James's interest in the navy brought him again to Portsmouth, when after his inspection of the yard, John Evelyn tells us, "His Majesty was entertained to a magnificent dinner." There are still standing two monuments to James II—the fine gateway at the entrance to the Officers' Recreation Ground, which originally stood in Broad Street, and the King's monogram on a bastion at the Camber Quay.

From the coming of William III (1689) down to 1815, for 126 years, there was almost continuous war with France, and during all this time Portsmouth was the chief naval centre; scarcely an admiral or general of note who did not at some time or another tread the streets of the old town. The number of ships in the navy was greatly increased, and enormous work thrown on the dockyard. In 1713 there were 240 ships of all kinds, in 1813 there were 722. Many acres of land and water were added to the dockyard. At the end of the seven years' war (1756-63) there was an Official Visitation, which recommended spending £350,000 on improvements; new docks were proposed, and it advised the use of stone rather than wood. The Admiralty Lords further "thought it highly important that all future additions, alterations, and repairs should be founded on certain fixed plans . . . proceeded on year after year in a regular manner."

George III was greatly attached to Portsmouth. In 1778 he appointed Sir Samuel Bentham—younger brother of the philosopher Jeremy Bentham—Director of the Dockyard. During Bentham's administration Marc Brunel's patent machinery for making blocks was set up in the yard. It was now possible for one man to do what ten had previously done in the same time; 100,000 blocks a year were soon produced. While Marc Brunel was living in the yard his famous son Isambard was born. Isambard's greatest feat was the building of the *Great Eastern*, the largest ship up to that time built, and for many years after. She was of 22,500 tonnage. It was due to Isambard Brunel's experiments that the screw propeller was adopted for warships.

The nineteenth century was a time of great change in the navy. It saw the passing of the sailing ship and the introduction of the steamship and the ironclad. The *Dreadnought* of 1805 was a wooden sailing ship of 2,000 tons; the *Dreadnought* of 1905 was a screw steel ship of 15,000 tons; the *Dreadnought* of to-day a steel ship of 27,500 tons, costing about £5,000,000. The area of the Dockyard is now over 300 acres, more than treble what it was 100 years ago. In 1759 there were employed in the yard 2,099 men; in 1783, 2,285 men; in 1890, 6,232 men, with a wages bill of £428,430; in 1910, 10,439 men, and wages £743,360. During the recent great war over 20,000 men were employed at one time.

The passing of time sees endless changes in the needs of the nation. The Yard, a few years ago busy beyond the limits of its capacity, is to-day nearly silent and empty. The star of the Royal Navy—or rather the Royal Dockyard—is not to-day in the ascendant.

The writer of these articles wishes to thank many friends for assistance and advice, and especially to acknowledge his indebtedness for useful information to books relating to Portsmouth, written by Mr. H. J. Sparks, Mr. W. H. Saunders, Mr. W. Gates, Mr. Monray Read, and Messrs. H. T. Lilley and A. T. Everett.

For the loan of blocks acknowledgment is due to the courtesy of Messrs. Charpentier, Ltd., Portsmouth.

## Victoria.

[FROM OUR SPECIAL CORRESPONDENT.]

### MELBOURNE UNIVERSITY SUPERANNUATION SCHEME.

THE University of Melbourne is about to adopt a superannuation scheme for all its full-time officers of every grade, which can only be described as generous and essentially sound. The university has made a capital grant at once, and will make an annual contribution of 2½ per cent. of the salaries paid, whilst the beneficiaries contribute annually 5 per cent. of the salary. The annual contributions of junior officers below 35 years of age are correspondingly graded. Professors will be able to retire at 60 years of age and other officers at 65 years of age; retirement is not, however, compulsory but optional. The maximum pension payable is one-sixtieth of the average salary for the numbers of years served, always provided that the pension payable shall not exceed £500 per annum. In the case of an officer leaving the service of the university before the retiring age he is entitled to withdraw from the fund all the moneys he has paid, together with 4 per cent. compound interest. Should the officer die within less than five years after retirement, the full pension will be paid to the widow for five years after the age of retirement. The scheme, which is guaranteed by the university and has been thoroughly examined by an actuary of recognized standing, appears to have given general satisfaction, and cannot fail to do something to remove some of the objections which have hitherto existed to service within a university.

### SECOND-YEAR EXAMINATIONS IN ANATOMY AND PHYSIOLOGY.

Under the extended and revised medical curriculum of the university second-year examinations in anatomy and physiology have just been conducted. There can be no question that the introduction of this examination has had a beneficial effect on the work of the students. Those who have been successful in the recent examination will enter on the further work of the third year in these important basal subjects of medicine under much more favourable conditions than formerly, and it is anticipated that the work of the third year will thus attain a higher standard than has been the case under the old curriculum.

### INCREASED UNIVERSITY FEES.

The Council of the University, after a long period of hesitancy and timidity, has at last ventured to raise the fees in medicine from about £23 per annum to £25. The fact, however, remains that it is still cheaper to send a boy to the university to study medicine than it is to educate him at a public school.

### CHANGES IN THE MEDICAL SCHOOL.

It is expected that the new anatomy department will be ready for occupancy about July or August, 1923. The evacuation of the existing anatomy buildings will enable the medical school library to be much more efficiently housed, and will also provide for some much needed extensions for physiology and pathology. It is hoped that the new department will be officially opened during the British Medical Association Congress (Australasia) which will be held in Melbourne in November, 1923. From a large field of local and overseas candidates Mr. J. Alexander Gunn, of the University of Liverpool, has been appointed director of tutorial classes in the University of Melbourne.

### THE STEWART LECTURES.

The last series of the triennial Stewart lectures of the University of Melbourne, recently delivered by Professor R. J. A. Berry, on "The Modern Psychology," have now been published by the university. Copies may be obtained from the Melbourne University Press at 2s. 6s.

## Scotland.

### COLOUR VISION.

At the meeting of the Royal Medico Chirurgical Society of Glasgow held on February 2nd an address on "Some recent work on colour blindness" was given by Mr. R. A. Houston, D.Sc., lecturer on physical optics in the University of Glasgow. In the course of his address Dr. Houston said that during the past eight years statistical surveys of the colour vision of

more than 2,000 students had been made at Glasgow University. They have already been described in papers in the *Proceedings of the Royal Societies of London and Edinburgh* and in the *Philosophical Magazine*, and the present lecture dealt with some of the principal results obtained. Frequency curves were shown representing the variation of the ability to discriminate colour about a mean. These demonstrated that normal variation covers almost everything as regards women but not as regards men. The colour-blind could not be regarded as an extreme case of normal variation. Trichromasy passed into monochromasy directly and not through dichromasy as an intermediate stage, as the original form of the Young-Helmholtz theory required, and the results of the investigation rendered untenable the latter theory and also the Hering theory. The final theory, when it came, would be a photo-chemical one, and the prospects of progress were at present very promising. The lecture was illustrated by lantern slides.

#### CENTRAL MIDWIVES BOARD.

At a meeting of the Central Midwives Board for Scotland, held for the election of office-bearers, Dr. James Haig Ferguson was unanimously re-elected chairman; Dr. Michael Dewart was elected deputy chairman; and Sir Archibald Buchanan-Hepburn, Bt., convener of the Finance Committee. The meeting appointed other committees and examiners, and approved the list of recognized institutions, with the teachers attached thereto, for the training of midwifery nurses.

At a meeting for the hearing of penal cases, with Dr. Haig Ferguson in the chair, a Glasgow midwife was cited to answer charges of serious breaches of the rules and misconduct. The Board found the charges to be proved and instructed the secretary to remove her name from the Roll of Midwives and to cancel her certificate, and in addition thereto the Board issued an order prohibiting her from attending women in childbirth in any other capacity.

## England and Wales.

#### THE NEW HASLEMERE HOSPITAL.

In a recent issue (January 27th, p. 169) we recorded briefly the formal opening of the new Haslemere and District Hospital by the Lord Chancellor, Viscount Cave. The need for increased hospital accommodation had been felt for some years, the old cottage hospital, opened in 1897, with its twelve beds, being quite inadequate for the largely increased population of the district. Early in 1920 it was decided to undertake a scheme of rebuilding, and an appeal was issued; but the offer of a new site led to the abandonment of this plan for enlargement in favour of the building of an entirely new hospital with ample room for future expansion. Upon the successful issue of this large undertaking, due in particular to Mr. W. E. Muir, Chairman of the Building Committee. The whole sum of £36,000 needed to complete the scheme had already been given or promised by the day of the opening ceremony.

The hospital stands on an excellent site of over four acres sloping towards the south, and its external design harmonizes with the surrounding residential property. The present accommodation provides thirty-one beds and four cots. The main entrance is on the east side, and the building has a long south frontage. Two wards project from the main block and form a sheltered court. The nurses' quarters are separated from the hospital proper by the kitchen and offices serving both departments; they have a private entrance, and communicate with the hospital by one doorway only on each floor. The main hospital corridor runs east and west, and leads to the male and female wards, each with twelve beds. There are also two single-bed wards on the ground floor, and one private ward for paying patients. The end of the corridor communicates with the two operating theatres (one large and one small), the x-ray room, dark room, and electrical treatment room. The first-floor corridor gives access to the labour and maternity wards and to another private ward. The building throughout has been designed in accordance with modern ideas of hospital construction: all corners are curved, and the skirtings form plain curves of the floor material. The walls of the hospital part of the building are of hard plaster. The corridor has a central gangway, four feet wide, of rubber sunk flush with the terrazzo floor. The floors of the wards, bathroom, ward kitchen, etc., are

covered with a jointless material and polished. The operating theatres are paved with terrazzo, and have white enamelled walls. The building is heated throughout with low-pressure hot-water radiators. Fresh air is admitted through the radiators and foul air is carried out in ducts to turret ventilators. The building is lit by electricity, with emergency gas-lights. The sterilizing room is fitted with a high-pressure steam sterilizer heated by gas.

The architects are Messrs. Read and Macdonald, and the medical equipment has been installed under the direction of Dr. Arnold Lyndon. On the evening after the opening ceremony the workmen engaged in building the hospital were entertained to supper. Dr. Lyndon, in acknowledging the toast of prosperity to the hospital, paid a tribute to the way in which the lay committee had supported the medical committee. There was nothing asked for by the doctors which was not freely given by the committee, and the medical staff had been allowed an absolutely free hand in getting anything they considered necessary. He congratulated all concerned upon possessing a thoroughly up-to-date and well equipped hospital.

#### THE POSITION OF PATHOLOGIST TO THE L.C.C. MENTAL HOSPITALS.

The Mental Hospitals Committee of the London County Council has been considering the terms and conditions to be attached to the appointment of a successor to Sir Frederick Mott, pathologist to the London County Council mental hospitals and director of the *Asylum Officers' Superannuation Act*, and the appointment is to be determined by three months' notice on either side, provided that the first year's service shall be on probation, and the appointment be terminable at the end of, or at any time during, that period without notice if the person appointed be found to be unsuited for the service.

#### SMALL-POX.

While small-pox has disappeared entirely from the metropolitan area and no cases remain in the Long Reach Hospital of the Metropolitan Asylums Board, cases continue to occur here and there throughout the county. It appears that at Clowne, near Chesterfield, there were on February 2nd a total of twenty-five cases, of which five had been reported that day. Not one of the victims had been vaccinated; the first cases of this outbreak were mild, but later cases have been much more severe, without being malignant. No deaths have been reported.

## Ireland.

#### PROFESSOR ELLIOT SMITH.

PROFESSOR ELLIOT SMITH, F.R.S., who delivered the Montgomery lecture at the Royal College of Surgeons in Ireland on January 29th, on "The movement of the eyes," was entertained to dinner the same evening by the President of the College, Sir W. I. de C. Wheeler. The following guests were present:

The Most Rev. and Right Hon. the Provost of Trinity College, the Right Hon. James MacMahon, the President, Royal College of Physicians, the President of University College, Mr. Leonard Abrahamson, Professor J. W. Bigger, Mr. Alexander Blarney, Mr. C. R. Boyce, Professor Boxwell, Mr. L. A. Byrne, Professor Caldwell, Sir Arthur Chance, Mr. Arthur Chance, Professor McDowell Cosgrave, Mr. T. H. Croly, Professor A. Dixon, Mr. O. H. Drennan, Sir Con. way Dwyer, Professor Evans, Professor T. H. Gordon, Mr. L. G. Gunn, Mr. T. G. Hardman, Mr. Arnold K. Henry, Professor G. J. Johnstone, Mr. R. L. Joynt, Mr. J. L. Keegan, Mr. A. MacConnell, C. J. MacAuley, Mr. R. B. Miller, Mr. R. C. I. Thomas Myles, Sir Lambie, Mr. Seton Pringle, Professor Scott, Mr. E. Sh., Mr. Henry Stokes, Mr. R. A. Stoney, Mr. J. B. Story, Sir Wm. Taylor, Sir Robert Woods.

## WAR MEMORIAL

TO

MEMBERS OF THE BRITISH MEDICAL ASSOCIATION WHO GAVE THEIR LIVES IN THE WAR,  
1914-1918.

It has already been announced that the Council of the British Medical Association has decided that the memorial to members who gave their lives in the war of 1914-1918 shall take the form of a Book of Honour to be placed in the library, a memorial tablet in the entrance hall, and a small book for issue to relatives describing the Book of Honour. Mr. F. G. Hallett, Secretary of the Conjoint Examining Board in England, has generously undertaken, as a labour of love to the profession, to illuminate the roll and superintend the engrossing of the names. He submitted to a meeting of the special committee appointed to make arrangements for the memorial a sketch of the first page or frontispiece of the roll, bearing a beautifully illuminated dedication. The scheme of the illumination was greatly admired and Mr. Hallett was asked to complete it. He was further asked to arrange that the work of engrossment should be proceeded with as soon as the list of names could be completed.

A list has been prepared which is believed to be complete, but it is of course very possible that some names may have been omitted. The first instalment appeared in our issue of January 20th (p. 125), and a further instalment is printed below. It is hoped that members will be good enough to look through the list and notify any additions or corrections that should be made, and, in particular, to verify the correctness of the christian names, as in some instances difficulty has been encountered in ascertaining them. Corrections or additions should be sent as early as possible to Mr. L. Ferris-Scott, Financial Secretary, British Medical Association, 429, Strand, London, W.C.2.

## Correspondence.

### GALEN.

SIR.—In reference to your interesting leader of February 3rd on Galen (in which, by the way, you refer very generously to my humble pioneer efforts to put him into an English dress), may I try to throw light on one point which is still somewhat obscure? You state very properly that the great masters of literature have all had the gift of selection, but you go further and affirm that Galen had not this gift. Well, it is true that he is often diffuse and unsystematic, and includes much matter that a more artistic perception would have eliminated. Yet must we not realize that when compared with his predecessors and contemporaries his advance was precisely in the direction of this artistic method of handling material? Galen is, after all, universally acknowledged to have been an eclectic and a synthesizer, and this can only mean that he chose the best elements from all the competing schools of medical thought and blended these elements into a unity. Observe how clearly he saw this principle of artistic selection at work in the animal organism or organic part; amongst the most fundamental of the "natural faculties" he includes one of attracting the appropriate (*δυναμὴς ἐλκτικῆς τοῦ αἰσίου*), and another of eliminating the inappropriate, the irrelevant (*ἀποκριτικὴ τοῦ ἁλλοτρίου*). Galen affirms repeatedly that it is by exercising these faculties that the living organism showed itself an artist (his constant phrase is, *ἡ τεχνικὴ φύσις*, the artistic, creative organism), and, although he may not state it in so many words, yet surely it is clear from the whole tenor of his writings that he recognizes the need for corresponding faculties being exercised in the conscious human sphere as well; in other words, he saw that these eclectic principles were as fundamental in psychology as in physiology.

Too true it is, as you say, that Galen left much uneliminated that ought to have been eliminated, but let us at least agree that he went a long way in the right direction. He did not select enough, and you are right in demanding, as the next step, selections from Galen. A word, then, on this point. Who is to give us the material from which to select? Who, in a word, is to put the rest of Galen into English? Is it not even conceivable to the academic powers that be that this man, who held the whole medical world spellbound for a thousand years, might at least be worth reading in our day? In any case, there do not seem to be as much funds available for such purposes as would do more than recoup the translator for getting his MSS. typewritten and posted to the publisher. Or, if there are such funds, I have never heard of them.—I am, etc.,

A. J. BROCK.

Edinburgh, Feb. 4th.

volumes, and I have ordered many of those which are in preparation. The format of the volumes is delightful (I prefer the leather binding), and the size admits of one being easily slipped into the pocket. The scholarship and printing are of the best. I find I could easily become intemperate in expressing my admiration for the library, and I think any doctor with the slightest tincture of the classics would find a volume of Loeb an excellent corrective for the worries of practice. The message is as fresh as on the day on which it was written, and an hour or two, occasionally, in the clear air of Ancient Greece has a tonic effect which few modern books can give, unless, indeed, a man is too fagged for anything but the latest "best seller."—I am, etc.,

Falkirk, Feb. 5th.

GEORGE C. STEWART.

### THE TREATMENT OF NON-MALIGNANT AFFECTIONS OF THE COLON.

SIR.—In his letter on the above subject which appeared in the BRITISH MEDICAL JOURNAL of December 16th, 1922, Major R. Kelsall, I.M.S., refers to Sir Arbuthnot Lane's quotation of my experience that certain Himalayan races enjoy a remarkable freedom from asthenic dyspepsia, gastric or duodenal ulcer, appendicitis, mucous colitis, and cancer. Let it be assumed that freedom from these diseases is common to all Eastern races, Major Kelsall has most opportunely recorded his own experience in Burma. He has found that the maladies above mentioned are not at all uncommon amongst the Burmese, Indians, and Chinese who seek relief at the various hospitals of that province. His experience is of great interest to me, for, having regard to the food habits of the people of Burma, it would have been perturbing to have heard that they exhibited an unusual freedom from gastro-intestinal disease.

The Himalayan races to whom I referred are exceptional both as to their food habits and their freedom from these diseases; so also are certain other races of Upper Egypt and Northern Nigeria. I referred to them in my Mellon lecture on "Faulty food in relation to gastro-intestinal disorder" with the object of contrasting the conditions of life of certain communities or races that are free, or comparatively free, from gastro-intestinal disease with the conditions of life of those that are not. I found an explanation of the unusual freedom of certain Himalayan races from such disease in their habit of using only the unsophisticated foods of nature. I venture to think that the faulty food habits of sufferers from gastro-intestinal disease in Burma will provide an explanation of its occurrence.

The genesis of these gastro-intestinal diseases is, to my mind, not a question of race, nor of East or West, but is pre-eminently one of the food habits of communities, of households, and of individuals. These diseases are common amongst the people of Southern India, a high proportion of whom live on the borderland of vitamin B insufficiency. Like the people of Burma, their staple food is rice—usually polished rice. It provides a supply of vitamin B that is insufficient for the needs of the body in general, and for the needs of the gastro-intestinal tract in particular. It is ill balanced, being too rich in carbohydrates and too poor in suitable protein.

SIR.—Your notice in the BRITISH MEDICAL JOURNAL of February 3rd of the Galen volume in the Loeb Classical Library impels me to try to discharge a small part of the debt of pleasure which I owe to the library. I bought the two volumes of Apollodorus, translated by Sir James G. Frazer, and since then I find myself the possessor of over seventy

The ill effects on the gastro-intestinal tract of food having these faults have been established by they are such as lead to the ultimate assimilative, and motor functions of the alimentary tract, and are the foundation upon which is built much of the gastro-intestinal disease so common at the present day.—I am, etc.,

Pastour Institute of Southern India,  
Coonoor, Jan. 14th.

R. MCCARRISON.

SIR,—I offer these suggestions with some diffidence, but I think the difference in Colonel McCarrison's experience and that of Major Kelsall is due to the fact that the people in one case were those living under normal outdoor conditions on the hills and those of the latter were chiefly from a large town.

I have never seen a case of appendicitis or gastric ulcer in an Indian woman. Indians are no doubt comparatively free from gastric and intestinal troubles—first, because they empty their bowels completely once or twice daily. One sees them sitting amongst their crops at dawn and at sunset for this purpose. They use the crouching posture—front of thighs against the abdominal wall and knees apart, the body supported on the balls of the toes. I think it will be found that this secures a more complete evacuation of intestinal contents than the position assumed by the European, or by those adopting European clothing and habits.

Every Indian is constantly drinking water—very often very bad water; in fact, as often as he urinates if he can he drinks water. This renders the normal bowel contents more putty-like, and the motion is evacuated in one long piece or is of the consistency of porridge.

The men in India as a race have excellent teeth. The women often have very bad teeth and suffer from constipation and toxæmia when pregnant. They do not drink as much water as the men, take little exercise, and lead sedentary lives. In my experience a woman who drinks plenty of water and is not constipated never has eclampsia.

That civilized people retain their faeces too long is probable. An enema given after a normal morning evacuation reveals too often that the intestines are full of faecal matter. Is it not possible that this retention of waste material from which toxins can be absorbed may be the cause of many diseases common to the civilized—dyspepsia, gastric ulcer, appendicitis, rheumatoid arthritis, migraine? I would also suggest that dental decay is intimately connected with unhealthy conditions in the intestine.

I think x-ray photographs of the bowel during defaecation on the Eastern and Western plans might give useful information. It is possible that the Oriental gut has no pathological kinks because it is properly emptied daily and washed out.—I am, etc.,

Lahore, Jan. 17th.

KATHLEEN VAUGHAN, M.B. Lond.

#### THE SURGERY OF THE PROSTATE.

SIR,—In your issue of January 27th I read the address of Sir John Thomson-Walker on "Some problems of prostatectomy" with the interest which the importance of the subject and the authority of the author demand.

In his reference to the renal complications of prostatic disease wise stress is laid on the necessity for a complete physical examination of the patient, and the fallacy of accepting laboratory figures alone as an index of renal function.

The relative merits of one-stage and two-stage prostatectomy are considered, a decided preference being shown for the two-stage method in cases complicated by chronic urinary retention or sepsis. I was under the impression that such cases were far from uncommon in every genito-urinary clinic until I read that two-stage prostatectomy is rarely performed by Sir J. Thomson-Walker, as cases complicated by chronic urinary retention or sepsis form only "a small minority of the cases of prostatic enlargement." His routine procedure in this respect I believe that of many urologists in this country, who of late years have become increasingly partial to the two-stage method. If it be agreed that the majority of these cases are potentially uræmic, the added margin of safety provided by preliminary suprapubic drainage of the bladder cannot be gaudied.

Now, as the Leeds school has recently shown, we owe the classical operation of suprapubic prostatectomy to McGill, its perfection to Freyer; and it is of this operation, perfected by Freyer and practised by surgeons everywhere to-day, that

Sir J. Thomson-Walker has some interesting criticisms to make. In his description of it he emphasizes as cardinal defects the obstacle of a rigid abdominal wall, the "primitive and unreliable method of controlling hæmorrhage by irrigation with hot water," and the danger of sepsis.

His description of the operation does not correspond exactly with that of Freyer, which, for the sake of accuracy, I have reread, after twenty years; it is to be found of course in his book, *Enlargement of the Prostate*, published in 1902. There we find no reference to the embarrassment of a rigid abdominal wall, and there can be few surgeons practising the Freyer method who are conscious of such difficulty in enucleation of the prostate. Given adequate elevation of the gland per rectum, and a supple finger within the bladder, the apex of the prostate is usually reached without "the considerable amount of force required to push the abdominal wall downward towards the pelvis."

Let us pass on for a moment to the question of hæmostasis in this operation. On this point Freyer is illuminating. An unrivalled experience of the operation led him to say, "there is, as a rule, very little bleeding, and this is easily controlled by irrigation with hot water." "Primitive" the method may be, in the sense of time-honoured; the fact that it is effective is of more consequence, but, we are assured, the method "would not be tolerated in any other operation of first importance." I believe the arrest of *post-partum* hæmorrhage from the uterus falls within this category, and the obstetric teacher of to-day, as of yesterday, not only tolerates but actually advocates its use.

One further defect, sepsis, merits consideration. The danger from the rectal finger is emphasized by reference to "changing the enucleating hand." Is it necessary to effect this change? Such a manoeuvre would certainly be more dangerous than the speculative risk of "direct infection through the rectal wall," of which there is no proof.

The solution of the author for these defects in the commonly performed prostatectomy of Freyer is its abandonment in favour of the open operation, which he describes in detail; it is by no means new, but in the practised hands of Sir John Thomson-Walker I am sure it is an ideal method. My attention was drawn to it several years ago by a paper emanating from the Mayo Clinic (E. S. Judd, 1916). Therein is figured and described what I take to be the American edition of the open operation. I tried it, and found it uncommonly difficult to perform with the aid of a forehead lamp, various retractors, and the Trendelenburg position; in all essentials a striking contrast to the directness and economy of means employed in the Freyer operation. In particular, the insertion of the continuous hæmostatic suture through the torn frill of vesical mucosa and prostatic capsule struck me as a gymnastic rather than a surgical exercise. Assuredly it is not an operation for the general surgeon.

Criticism comes easily to one who writes from a brief. And a perusal of Sir John Thomson-Walker's address prompts the thought that in his brief for the open operation he has done less than justice to the merits of the older and classical operation by the method of Freyer.—I am, etc.,

Dakinfield, Cheshire,  
Feb. 5th.

GERALD RALPHS,  
Assistant Surgeon,  
Ashton-under-Lyne Infirmary.

#### POLIOMYELITIS AND ENCEPHALITIS LETHARGICA.

SIR,—Having had the opportunity of meeting, under the most cordial circumstances, the then Chief Medical Officer of the Local Government Board, Sir Arthur Newsholme, during the epidemic at first called "botulism" in the spring of 1918, my interest in the whole matter of this extraordinary malady has led me to follow its subsequent course in England. Obviously not the least important aspect of this subject is that of the true nature of the peculiar disease. Now there still is great difference of opinion on this point. But on reading over the report of the Local Government Board, which included my report to our Surgeon-General, and also after reading the new monograph on encephalitis lethargica and certain recent British literature, I am rather surprised to find that there has been some misunderstanding of my attitude on the matter of diagnosis. When I finished the survey of those cases which I was permitted to see by Sir Arthur Newsholme in London and the Midland cities, I came away feeling that I had observed what was tantamount to the second or third month stage of an epidemic of poliomyelitis. This point I stated clearly in my report. In that

same communication, notwithstanding the fact that I had found many cases of muscle atrophy which had gone undetected, and which led me to feel that the disease was poliomyelitis, I also intimated that the characteristics which made it seem unlike that disease—namely, those that had to do with the higher centres, and from which it drew its name, encephalitis—were also present.

In my report I carefully avoided taking the flat position as to whether the disease was encephalitis lethargica or poliomyelitis, and intimated that there was no way—save, perhaps, further animal experimentation—of determining whether the two were different expressions of the same disease, or actually two different diseases. Dr. F. G. Crookshank has, from the very first, held the position that no categorical distinction can be made between cases of "poliomyelitis" and cases of "encephalitis lethargica," and his original articles on the subject, as well as subsequent ones, have never been given adequate consideration by the public authorities, or by the journals. Notwithstanding the fact that experimental work under the direction of Dr. Flexner at the Rockefeller Institute has failed, so far, to establish immunological relationship between the two diseases, encephalitis lethargica and poliomyelitis, one cannot help being impressed, from the clinical standpoint, with the very great similarity of the two afflictions. We are having a good deal of this disease now in sporadic form in the neighbourhood of New York City, and I have recently seen many cases which one might justifiably classify in either category.

In view, then, of the still clouded state of our understanding of this remarkable affliction, which may involve the whole or any part of the central nervous system, it is difficult to comprehend why some medical journals have so unfortunately increased the fog by emphasizing one conception of the disease to the exclusion or misrepresentation of others.—I am, etc.,

New York, Jan. 16th.

GEORGE DRAPER.

### THE WHITE MAN IN THE TROPICS.

SIR,—In your issue of November 4th, 1922, there appears a note on the subject of the residence of white people in the tropics and a reference to the Northern Territory of Australia. May I briefly state the facts? So far as scientific investigations have gone in Queensland, it has been impossible to find any evidence of organic changes produced in human beings by high temperatures alone. There are, however, in Queensland few tropical diseases and only a negligible coloured population. The vital statistics of Queensland are extraordinarily good, as the following statement will show.

TABLE I.—Showing the Rate of Growth of White Population in Australian Tropics.

Date of Census.	Population of Tropical Portion of			Total Population of Tropical Australia.
	Queensland.	Northern Territory.	Western Australia.	
April 4th, 1881 ...	56,011	3,451	651	60,153
April 6th, 1891 ...	103,986	4,898	3,711	117,595
April 1st, 1901 ...	145,932	4,036	4,664	154,742
April 3rd, 1911 ...	157,112	3,310	4,598	165,420
April 4th, 1921 ...	181,123	3,709	4,443	189,275

It will be seen that the population of Tropical Queensland increased by 24,011, or 15.28 per cent., during the decennium 1911-21. The rate of increase compares very favourably with that experienced by the Commonwealth as a whole, the results for which showed, for the same decennium, an increase of 9.11 per cent. in respect of rural areas, and 19.10 per cent. in respect of provincial urban areas.

It may be of interest to note that in 1881 the tropical population of Queensland represents 28 per cent. of the total population of that State, the corresponding percentage at succeeding censuses being as follows: 30 per cent. in 1891, 31 per cent. in 1901, 27 per cent. in 1911, and 25 per cent. in 1921.

The particulars here furnished relate to all that portion of each State north of the tropic of Capricorn.

The scanty population in tropical Western Australia and the Northern Territory is due to economic causes. Tropical Queensland is just as hot as the Northern Territory and nearly as hot as the northern part of Western Australia.

TABLE II.—General Mortality and Infant Mortality Rates for the whole of Queensland.

Year.	General mortality rate (No. of deaths per 1,000 of mean population).	Infant mortality rate (No. of deaths under 1 year of age per 1,000 births).	Year.	General mortality rate (No. of deaths per 1,000 of mean population).	Infant mortality rate (No. of deaths under 1 year of age per 1,000 births).
1911	11	65	1916	11	70
1912	11	72	1917	10	54
1913	10	63	1918	10	57
1914	10	64	1919	12	72
1915	11	64	1920	11	63

In respect of general mortality, it may be noted that for each of the years specified Queensland was below the Commonwealth average on six occasions, and above it on the other four. In respect of infant mortality, Queensland was below the Commonwealth on nine occasions, and above it on one only.

It will be noticed that both adults and infants have a better chance of living in Queensland than in the Commonwealth. The whole of Queensland is north of 29° lat. S., and the greater part of it is north of the tropic of Capricorn. May I ask your readers to name any country blessed with a temperate climate which shows a better vital record?

I shall be grateful if any of your readers can give me any valid reason for the belief that coloured people suffer less than white people from heat. It is, of course, true that for the most part people in the tropics are dark and people in temperate latitudes are fair, but it is not universally true—for example, the southern Chinese are yellow and not black, and in the Pacific, as is well known, the Melanesians and Polynesians differ greatly in colour. Physically it would seem that the dark skin should mean a quicker response to heat by more rapid absorption. My own experience, however, of the tropics has been that the principal difference lies in the manner in which the coloured man adapts himself to the climate by discarding his clothing.—I am, etc.,

Melbourne, Australia, Dec. 28th, 1922.

JAMES W. BARRETT.

### THE DANGEROUS DRUGS REGULATIONS.

SIR,—These regulations are justified only on the principle that politicians need jobs and secretariats require food at the cost of that most patient of animals—the taxpayer. The British maxim used to be that laws were not made to bind honest men but to bind the villain of society. This is all being altered, and laws are being made to bind every member of society, and are being gradually pressed home until we will shortly receive Government orders for every act in our natural lives, except the act of being born and the act of dying.

This drugs order is most absurd. It used to be a maxim of economics that no tax should be levied unless there was a reasonable prospect that it could be economically collected—that is, that the cost of collection should not exceed the revenue collected. It was also a maxim of statecraft that no law should be made which could not be enforced. The medical law should be made which could not be enforced. The medical profession, like any other large body of men, has got a few villains. This dope law binds the honest man as well as the villain. It not only binds the former—it insults him. He objects to it, but he is far too patient. He does not object near enough. He should see to it in the future election of British Medical Councils, etc., that he elects men who will represent him, and not councils which will be the creatures of Government secretariats who only help the politicians to barter the liberties of honest men.

Will this dope order be effective? This is the grand issue; if not effective, it is the work of charlatan "statesmen"; to be effective, it has clearly to be efficient with the few villains of the profession—it cannot be effective with those who are not offenders, who are the great mass of the profession.

Assume that in defending the dope-taking degenerates against themselves Dr. A. is an offender: he is, so to speak, degenerate, too. Has degenerate Dr. A. any scruples about the methods he uses to evade the order? He has only to write up his register—falsely, of course—and no gentleman of the secretariat can detect him. His register shows a large opium thalamic practice which justifies the use of a large amount of cocaine. His register shows a large medical practice and requires a large amount of opium, etc. The opium and cocaine may be used for dope purposes, but this will not be

shown by his register when a committee comes to deal with him. Their honest verdict will be suspicion that the drugs are used for dope purposes, but not proven, and the case falls through. The dope order will not effect its object.

Take the "dry law" in the U.S.A., which is on the same footing, except that it deals with a very large body of the community who are not degenerate. Is it effectual? It has not lessened drink for those who can pay for it.

If the ordinary law of the land cannot cope with this question, this inquisitorial law will not.—I am, etc.,

HENRY SMITH, C.I.E.,

Lieut.-Colonel I.M.S. (retired).

Sidcup, Kent, Jan. 29th.

# RADIOTHERAPY FOR CANCER.

SIR,—I have only now had the opportunity of reading Mr. Fitzwilliams's paper in your issue of January 20th, as I returned but a few days ago from a second visit to Erlangen to study the recent developments there in that very deep x-ray therapy, principally which Mr. Fitzwilliams writes the same category with violet paste, and other so-called "cures" of cancer.

Surely such an attitude is most unfair, and discouraging to research, though it is true that immediately following his diatribe against any of the attempts at treatment, as an alternative to surgical removal of malignant growths, he does say, "Investigation and experiments should and must continue; I should be the last to decry them." He then goes on to imply that the medical profession is Athenian-like in its desire for "some new thing."

Now it is an interesting coincidence that, in your issue of January 27th, there is a report of a meeting of the Medical Society of London on the x-ray treatment of malignant disease, and, though different speakers held varying views as to the extent of relief that might, as yet, be expected from radiotherapy—"deep" or ordinary—of malignant disease, yet the consensus of opinion of both surgeons and radiologists seemed to be unanimous as to the benefits of radiotherapy after an operation for cancer.

Now on what do these benefits depend? Obviously because the rays have a lethal action on any malignant cells that may have escaped the surgeon, and which therefore form a focus for a so called recurrence. If, therefore, rays can destroy malignant cells when scattered near the surface, it only requires that these rays be made more and more penetrating—in fact that they approach the gamma rays of radium—and that apparatus and x-ray tubes be devised to produce them in sufficient quantity and for a sufficient time to allow them to act for this same lethal effect to be produced on malignant growths en masse.

Much has been written on this deep therapy, and in January of last year you published a paper of mine on the subject, after my first visit to Erlangen. Steady progress has been made there at the expense of much time and money, and with a most complete organization. It is unfortunate that, to obtain these penetrating rays, "larger and more expensive instruments" are necessary, but that is no reason why a carefully thought out scientific method of endeavouring to treat malignant disease is to be classed with quack nostrums. Mr. Fitzwilliams says he is the last to decry investigation. Certainly paragraphs 4 and 5 of his otherwise interesting paper are the last things to encourage research.

However, in spite of the gibes of Mr. Fitzwilliams and of any followers he may have, research and investigation will go on, at any rate on the Continent, where the mental attitude on the treatment of malignant disease is broader than it appears generally to be in this country.—I am, etc.,

J. CURRIS WEBB,

Honorary Radiologist, Gloucester Royal Infirmary.  
Cheltenham, Jan. 29th.

# HOSPITAL POLICY.

SIR.—Dr. Garratt's letter (February 3rd, p. 211) emphasizes the difficulty that meets any attempt to differentiate payments made by patients, and it overlooks a most important premise in the Council's Recommendation (SUPPLEMENT, BRITISH MEDICAL JOURNAL, November 18th, 1922, p. 187) that "all payments made for hospital benefit . . . are in fact payments towards all the services of the hospital," as I feel sure Dr. Garratt will concede they must be, and there is no attempt made in hospital accounts to separate contributions into parts for treatment and otherwise.

It would be well at the outset to know exactly what is included under the term "maintenance and accommodation"; we are told that it is only the "bare necessities of life," which, however, cost 30s. a week, but in a previous letter (December 23rd, p. 1196) it is stated that the working man has no difficulty in providing this maintenance and accommodation at home. Is it really suggested that these items in the expenditure of a working man with an income of 40s. or 50s. a week amount for any one member of the family to 30s. or even 20s. a week? Would anyone contend that the maintenance and accommodation found in a hospital, costing, say, 20s. to 30s. a week, is not incomparably better, especially from the point of view of the sick person, than that found in an ordinary working man's home, and that it is not an essential and integral part of most treatment? Could it be held that given the necessary medical and nursing staff and apparatus treatment would be as successful in a hospital patient's home, with the surroundings, air space, food, and service provided there, as it would be in the hospital?

No objection is raised to the assessment for a staff fund of money from a working man's contributory scheme because, we are told, "there will almost always be some definite financial arrangement between the contributor and the board." This arrangement of course applies to every unit contributing to the fund; is there not implied a similar understanding between the individual patient who pays and the hospital? Payment by a patient is not a charitable contribution, but for services rendered.

I would like again to ask whether it is intended in the case of a payment which exceeds the agreed amount for maintenance and accommodation that the sum assessed shall be the whole amount paid or only the excess.

No, I certainly would not attempt at the present time to approach any hospital board with our proposal, and I hope that no one will do so until we have arrived at a fairly general agreement among ourselves. It is a great thing that even the opponents of the Association's policy are now coming to admit that staffs of hospitals should receive at any rate some payment, and I am convinced that it will be possible before long to formulate a policy which shall have the practically universal acceptance of the profession; but it can only be arrived at by friendly discussion both in meetings and in the press.—I am, etc.,

Bradford-on-Avon, Feb. 5th.

CHAS. E. S. FLEMING.

# RAGGING IN BOYS' SCHOOLS.

SIR,—I think that there can be no doubt that bullying of a more or less objectionable type, now called ragging, does go on at a certain number of boys' schools. I have at the present time under my care a boy who had run away from a public school, and who when I saw him first was in a highly nervous and cowed condition. The whole matter is under investigation by the school authorities, and active steps will undoubtedly be taken to stop any bullying that may be going on. The average healthy boy can face his day's troubles all right, but it is when the boys go to their dormitories at night in charge of senior boys that serious consequences may arise to the boy's health, mentally, morally, and physically, if bullying is then continued. I seriously hope that all medical men who are consulted by parents as to a school for their boys will strongly advise them to inquire very carefully as to what supervision is exercised over the dormitories at night by the masters. At some schools the senior boys may be 19 years old, and it is a question whether paragraph 12 of Part II of the Prevention of Cruelty to Children Act, 1908, would not come into force; at any rate it is a serious menace to the national health.—I am, etc.,

HOWARD M. STRATFORD, F.R.C.S. Edin.

London, W., Feb. 3rd.

AN International Congress of Thalassotherapy will be held at Venice from April 9th to 12th. Titles of papers should be sent to the General Secretary, Professor Ceresole, Ospedale Civile, Venice, before March 15th.

THE thirty-fifth German Medical Congress will be held in Vienna from April 9th to 12th, under the presidency of Professor K. F. Wenckebach, when there will be discussions on encephalitis lethargica, introduced by von Economo of Vienna and Nonne of Hamburg; and on high arterial blood pressure, introduced by A. Darig of Vienna and Volhard of Halle. One afternoon will be devoted to demonstration of patients with endocrine disturbances.

## Obituary.

JAMES RITCHIE, M.A., B.Sc., M.D., F.R.C.P. EDIN.,  
Professor of Bacteriology, University of Edinburgh.

We had the sorrow last week briefly to announce the death of Professor Ritchie of Edinburgh on January 28th, after a long and distressing illness.

James Ritchie was born in 1864, and was the only son of Rev. W. Ritchie, D.D., of Duns, an eminent minister of the United Presbyterian Church. He was educated first at the Royal High School, Edinburgh, and later, in arts and medicine, at the University. By the time he graduated in medicine at 24 years of age he was already recognized by his teachers and fellow students as one for whom the future contained rich promise. In addition to honours at graduation he had the much coveted distinction of being appointed one of the Presidents of the Royal Medical Society. He was a resident surgeon in the Royal Infirmary in charge of Professor Chiene's wards. He graduated M.B., C.M. with honours in 1888, and took the degree of B.Sc. in Public Health in 1889. In the same year he went to Oxford to act as assistant to Mr. Horatio Symonds, F.R.C.S. In this post he continued for a number of years and gained a wide clinical experience, but the Oxford laboratories attracted him and he took up the study of pathology and bacteriology. He had in this the encouragement of Sir Henry Acland.

Research led to teaching and writing, and by 1895 he was giving instruction in bacteriology; in this year also he obtained the degree of M.D. Edin. and was awarded a gold medal for a thesis entitled, "Some contributions to the theory of germicidal action." In 1897 he published, with Professor Muir, a *Manual of Bacteriology*. This was from the first, and has remained, the standard English textbook on the subject. Sir John Burdon-Sanderson succeeded Sir Henry Acland in the Regius Chair of Medicine, and one of his first acts after his appointment was to arrange for a three-term course in pathology and bacteriology for the medical curriculum at Oxford. It fell to Ritchie to undertake the greater part of the teaching. Further developments naturally followed. He was first lecturer, then reader, and finally, in 1902, was appointed professor of pathology. During this time a new department was built under his direction. His work as a professor was most successful. The undergraduates were his enthusiastic disciples; his weight in all educational questions was recognized by his colleagues in the University, and he was elected to a Fellowship in New College. His Oxford period came to a close in 1907, when he returned to Edinburgh to take the post of superintendent of the Laboratory of the Royal College of Physicians; in 1913 he was appointed to the Chair of Bacteriology in the University.

This bald recital of the posts which he held is itself ample evidence of the kind and amount of work which Ritchie found it possible to undertake. He was never afraid of responsibility, and in what he did he had most exact methods of working, and ceaseless application. In teaching he was clear and stimulating; he came into close personal touch with his students, and he drove his teaching home with many a humorous stroke; he was held in much affection by all whom he taught. The subjects of his own researches were chiefly bacteriological; they included prolonged investigations into the nature of bacterial toxins and the relation of their harmful action to their chemical constitution; the nature of the immunity reaction; and the application of antiseptics. He inspired and trained numerous younger men to follow his footsteps, and his help and criticism were sought by workers in many medical schools.

He had a ready pen. The early interest in literature and philosophy which led him to take the M.A. Edin. in 1884 remained through his life, and the power of clear scientific exposition which he acquired lent a note of distinction to all his writings. In 1913 he edited with Professor Pembrey a textbook on *General Pathology*. It was an important contribution to the science by a group of authors in this country, and the volume included illuminating chapters on "Tumours," "Atrophy and Hypertrophy," and "Death," which he himself had written.

When the Pathological Society of Great Britain and Ireland was founded in 1906 Ritchie was appointed a secretary along with Professor Boycott. The success of the society is largely due to the genial enthusiasm and efficiency with which he gave himself to the work of his office. In 1908 a working

arrangement was made by which the *Journal of Pathology and Bacteriology* became the official organ of the society, and Ritchie became one of the editors with Professor Sims Woodhead. For this duty he was singularly well fitted: his wide knowledge of the subject in all its branches, his business capacity, his tact in dealing with contributors, and his keen appreciation of expository style made him an ideal editor. Needless to say, the journal prospered wonderfully under his care.

In the Medical School of Edinburgh he had a profound influence. For the Royal College of Physicians, the Royal Infirmary, and for the University he did endless service. He was one of those who originated the movement to establish in Edinburgh a memorial to Lord Lister. This was designed to provide an institution arranged and equipped for medical research in a form which would unite the forces of the various medical corporations in its comprehensive purpose. No sooner had the scheme been announced and the first steps taken to carry it into effect than the great war broke out. It was one of the greatest disappointments of Ritchie's life that he was not spared to see the development of the scheme.

He was ever on the side of progress, and into any duty which he undertook he managed to convey something of the idealism and enthusiasm by which he was inspired. In all the different offices he held he found many who relied on his judgement with implicit confidence, and not a few who claimed the privilege of friendship. His loyalty, steadfastness, and sympathy were unflinching.

His wide circle of friends, to whom his untimely illness and death brought the deepest sorrow and regret, express the most heartfelt sympathy with his widow and daughters.

J. LORRAIN SMITH.

Professor Muir of Glasgow University writes:

As Professor Ritchie was my intimate friend from the days when we sat together in the junior Latin class in Edinburgh University in 1880, it is fitting that I should add something to the account of his life.

James Ritchie was a son of the manse, and was brought up in an atmosphere of culture and piety; the impress of this was deep and permanent. Educated at Edinburgh High School and afterwards at Edinburgh University, where he graduated M.A. in 1884, he had the advantage of entering on the study of medicine with a well trained mind and liberal outlook. As a student of medicine, he was recognized by his fellows as a man of great ability and strong personality; he won many distinctions and graduated with honours. He had a strong bent towards the scientific side of his profession, but for a year or two after graduation it was not clear what line he would follow; he might have excelled in any department. It was after he went to Oxford as assistant to Dr. Horatio Symonds that his life's work was determined. Taking up pathological work at the Radcliffe Infirmary, he attracted the attention of Sir John Burdon-Sanderson, whose friendship and help Ritchie ever acknowledged with gratitude, and it was at his request that he started classes in pathology. When he went to Oxford there was no regular teaching of the subject. When he left it in 1907 he had been made professor, and a modern pathological institute had been built and equipped; and though he was helped by Burdon-Sanderson in every possible way, this was essentially his own doing, and it was a wonderful achievement. He had, moreover, remarkable success in teaching. His classes attracted a constantly increasing number of the best students, and not a few owe to him their earliest interest in pathological science. It is sufficient to mention that men such as Boycott, Dean, and Turnbull were among his pupils. In Edinburgh his gifts as a teacher have been equally prominent, and few men have inspired so much devotion in their pupils.

While fully recognizing the importance of morbid anatomy and histology, Ritchie realized the enormous advances which were being made in other fields. Especially was this the case with bacteriology, and it was with a view to bringing recent discoveries in this subject into relation with pathological processes that he and I wrote the *Manual of Bacteriology* which was first published in 1897. Here I should like only to say how much, in working with him, I came to admire both his critical judgement and the painstaking labour which he devoted to his share of the work. At a time when new work was being rapidly published, it was a matter of no small difficulty to distinguish wheat from chaff, but Ritchie's instinct was rarely at fault. His broad view of pathology is further illustrated in the *Textbook of General*

*Pathology*, which was edited by Dr. Pembrey and himself, and published some years later. The chapters were written by pathologists, physiologists, and physicians, including the editors, and the object was to set forth the results obtained in different departments, so far as they bore on the problems of disease. In this way the work has been of great value. From an early period Ritchie saw clearly that pathology was not to be studied by any one method, but that all possible methods must be used, and that, for the best ultimate results, work in different fields must be co-ordinated. How true this view is, has been abundantly shown in recent times.

Few men nowadays are so science as Dr. Ritchie was. knowledge of bacteriology in public health. He was an expert in kindred sciences, and he had considerable experience as a physician. Both as an investigator and as a director of research he held high rank, his own investigations dealing chiefly with wide problems in immunity and antiseptic action. In the systematic exposition of a subject and in critical analysis he had few equals, and here I may refer, in addition to the textbooks mentioned, to his review of the subject of immunity published in the *Journal of Hygiene* in 1902, and to his masterly article on the General Pathology of Infection in *Allbutt and Rolleston's System of Medicine* (second edition).

The unstinted way in which Ritchie devoted his powers to any work which he undertook is strikingly illustrated by his services to the Pathological Society of Great Britain and Ireland. He was one of its secretaries from the foundation, and when the *Journal of Pathology* was adopted as its official organ he became assistant editor, and, on the death of Sir German Sims Woodhead, editor of the journal. The work which he did, both on the scientific and business sides, was invaluable; for along with his critical ability, always used with courtesy and tact, he had a special knowledge of the technical side of publishing, which was of great advantage. I am sure that all the members of this society will acknowledge that to him the success and efficiency of both society and journal were largely due, and will always gratefully remember the debt they owe to him.

In later years his gifts for administration brought him new duties in other spheres. He was never a lover of office for its own sake, but he was always responsive to the appeal of any good cause. As a member for several years of the Board of the Royal Infirmary in Edinburgh, and more recently of the University Court, he took a leading part in furthering the work of both institutions, and gained the unreserved trust of his colleagues. Always zealous for progress, he was helped to it by his fair-minded, kindly, and unselfish dealing.

Professor Ritchie had a wide circle of friends—he loved their companionship. He was not cloistered in his own profession, and many grieve at his death whose work lay wide apart from his own. He was intensely human in his outlook, humorous and wise, interestingly informed, and sympathetic; witty also—his skill in word portraiture and epigrammatic terseness in description will not soon be forgotten. He rejoiced in the advancement of his fellows, and nothing that he did ever savoured of the petty or the unworthy. The foundation of all the affection felt for him was well and truly laid. He has left a noble record of good and useful work, but those who knew him best will dwell most on what he was. His

family life was a peculiarly happy one, and was for him a priceless possession. He bore the trials of his last illness with marvellous courage and patience, and he died, as he had lived, in calmness and confidence.

Professor ARTHUR THOMSON of Oxford has been good enough to send the following appreciation of Ritchie's work for the University of Oxford:

To those of us at Oxford who were associated with him in the days gone by, the death of Professor James Ritchie of Edinburgh recalls how much the medical school was indebted to his initiative and enterprise whilst he was our colleague. As I write this away from sources of accurate information, I must content myself with a general outline of his career whilst he was with us. Coming to Oxford about 1890, as a young man with surgical tastes, he became associated with Mr. Horatio Symonds, the well known surgeon, whose death we have had so recently to deplore.

In this capacity he was brought in contact with the staff of the Radcliffe Infirmary and with those concerned in medical education in the University. At this time the medical school was in process of development under the inspiring influence of Professor Burdon-Sanderson, who was ever alert to recognize ability and utilize it to the best advantage. Under Burdon-Sanderson's guidance Ritchie was early attracted to the study of pathology, and soon made rapid strides in his knowledge of that subject.

When Sir Henry Acland resigned the Regius professorship of medicine, after much pressure, and despite the adverse comments of some, Burdon-Sanderson accepted the responsibility of filling that chair. This he did with the declared intention of devoting himself to the furtherance of the study of pathology, for which at that time the University made no provision. He was most ably supported by the energy and ability of young Ritchie, who threw himself heart and soul into the project. For long they struggled against adverse conditions, with but slight encouragement from the University, and but little sympathy from the Oxford medical

PROFESSOR JAMES RITCHIE.

[W. Crooke, Edinburgh.

graduates in London, whose contention was that Oxford was ill adapted for the pursuit of that study. Happily, when the future seemed to hold but little prospect of success, Mr. Ewan Fraser, then a pupil of Ritchie, offered us the munificent sum of £5,000 towards the erection of a department of pathology. The University, in duty bound, and in response to the crying needs of a growing school, provided the additional funds, and thus were laid the foundations of a subject which has since been taught at Oxford with ever-increasing advantage to its students and with recognized distinction by its teachers. It is not belittling the fame of Sir J. Burdon-Sanderson to say that Ritchie was the moving spirit in planning the new buildings and directing the teaching of the department of which he was subsequently placed in charge as titular professor of pathology.

Under Professor Ritchie's influence a school of pathology was soon founded, many of whose pupils have since risen to distinction, but unfortunately there was no permanent endowment associated with the chair, and the future was to some extent precarious. Under these circumstances it is not to be wondered at that, attracted by the inducements held out by the late Sir Batty Tuke, Ritchie, about 1907, accepted the directorship of the Research Laboratories of the Royal College of Physicians of Edinburgh. To us it was a sad

wrench; to him, I know, the decision was only taken in spite of the dictates of his heart, but the claims of his fatherland and his Alma Mater proved paramount, and he answered to what he regarded as the call of duty. What was our loss has proved Edinburgh's gain. When, alas, too late to retain his services, a couple of years after he left us a chair of pathology was instituted and endowed by the University, and the future of the subject was thus assured.

Meanwhile during his sojourn in Oxford Ritchie's abilities had been quickly recognized in other directions; he was given a Fellowship at New College, and in due course became a physician to the Radcliffe Infirmary. There his activities did much to place on a permanent footing the *entente* established between that institution and the University, particularly in respect of the facilities necessary for the teaching of pathology. It is in grateful recognition of these services that those of us interested in the welfare of the Oxford Medical School desire to place them on record. Of his personal qualities, as one of his oldest friends I write feelingly. He was a "white man" in every sense of the term. With high intellectual attainments and lofty ideals he combined a soundness of judgement and an insight into business which in my experience are unusual. He had within him the makings of a statesman but withal was simple, modest, and a lover of all that was good and pure. In the interests of the school he worked with untiring energy, often sacrificing his own personal claims, for the common good. Of his virtues as a colleague I can only write with feelings of profound respect and admiration. In lighter vein his pawky Scottish humour just bubbled over. When on occasions in debate he took the floor at the meetings of the Oxford Medical Club, his incisive criticism and brilliant repartee, often delivered in the broadest Doric, never failed to arouse the attention or stir the feelings of those who were privileged to hear him. Of Ritchie I never heard a man say an ill word—a tribute which few can claim.

By his death—alas! all too soon—Oxford shares with Edinburgh the sorrow entailed by the loss of a man so gifted and lovable. With us his memory will ever be associated with the early development of the medical school. To Ritchie we owe more than most men know. May it not be forgotten.

To his bereaved widow and sorrowing family we tender respectfully our sincere sympathy and regret for the loss of the man who helped us much.

Dr. F. E. REYNOLDS, Senior Lecturer in Pathology, University of Edinburgh, writes:

Although the name of Professor James Ritchie will go down in the history of the University of Edinburgh as a great scientist, worker, and teacher, it is even more for his personality that those of us who have been his undergraduates or workers in his laboratory will treasure his memory. The keen interest he had in each of his students made us feel that in him we had a personal friend who shared with us our joys and successes, our difficulties and sorrows. Nothing was too much trouble for him to do on our behalf. Although so fully occupied by his professorial and other duties, he was never too busy to give us freely of his advice and help both as a man and as a scientist. As with all truly great men, patience, simplicity, and humility were outstanding features of his character.

Professor Ritchie's death has caused a gap in the lives of his students and of his assistants that can be filled only by the memory of his many acts of personal kindness to us all. When our time comes to pass, may we be able to say with as much justification as he could have said: "I have upheld the honour and dignity of my profession; by my work and industry I have added to the great reputation of my university; I have helped my fellow men to the utmost of my ability."

Dr. ERNEST W. M. HIGGS of Oxford died from broncho-pneumonia on January 9th, aged 52. He was a native of Bodmin and received his medical education at Charing Cross Hospital Medical School and took the diplomas of M.R.C.S. and L.R.C.P.Lond. in 1891 and the L.M.Dub. in 1892. After serving as demonstrator in minor surgery and house-surgeon at Charing Cross Hospital, he became surgeon to the Royal Niger Company, West Africa, and commenced practice in Oxford in 1900. Early last year, in consequence of a severe accident sustained six years before, he underwent high amputation through the thigh. An artificial leg was fitted, in the use of which Dr. Higgs became adept; he was able to drive his car as before and continued much of his professional and public work. He was a member from its

inception in 1912 of the Oxford National Health Insurance Committee, and had served on the medical service, allocation, and finance subcommittees. During the war Dr. Higgs was one of the examining members of the local medical board. He was a member of the Executive Committee, and was this year chairman, of the Oxford Division of the British Medical Association. He is survived by his widow and two sons. The funeral took place at Rose Hill on January 11th.

We regret to record the death, at Lisbon, of Dr. THOMAS WOOD of Leith, who had been ill for several months and was on his way to the Canary Islands. Dr. Wood graduated M.B., C.M. in 1883, and M.D. (with commendation) in 1904, at Edinburgh University. He was a well known general practitioner in Leith, was a Fellow of the Royal Society of Edinburgh and of the Obstetrical Society of Edinburgh, and held the appointment of factory surgeon. His principal public work was performed in connexion with Leith School Board, of which he was a member from 1894 to 1909. He took a large part in the provision of school extensions, and was particularly identified with the introduction of the medical inspection of school children, which was carried out in Leith for a considerable period before legislation made it general in the rest of the country. In his younger days Dr. Wood was a keen Volunteer, he was a justice of the peace for the county of Midlothian, and he was a member of the Edinburgh and Leith Division of the British Medical Association. He was the author of several contributions to medical literature, chiefly on subjects connected with obstetrics and public health.

We regret to record the death, following an accident, of ALFRED HENRY FISON, D.Sc., who had been Lecturer in Physics at Guy's Hospital since 1906, and at the London Hospital since 1910. He was born in 1857 and received his early scientific education at the Royal School of Mines. For more than twenty years he travelled about the country giving university extension lectures, and he had been secretary of the Gilchrist Educational Trust since 1912. Dr. Fison's great ability as a teacher was recognized by generations of students, many of whom caught something of his enthusiasm for physical science.

## Universities and Colleges.

### UNIVERSITY OF OXFORD.

THE Representatives of the University at the Conference on the Courses of Instruction Provided by Medical Schools, held at the University of London on February 3rd, were the Regius Professor of Medicine (Sir Archibald Garrod) and the Dean of the Faculty of Medicine (Dr. E. W. Ainsley Walker).

## The Services.

### R.A.M.C. COMMISSIONS.

THE following were the successful candidates for commissions in the Royal Army Medical Corps at the competition held in London last month: H. A. Gilkes, M.B., Ch.B.Oxf., R. Murphy, B.A., M.B., B.Ch., B.A.O.Dub., F. C. H. Sergeant, M.B., Ch.B.Liverp., W. L. S. Cox, M.R.C.S.Eng., L.R.C.P.Lond.

### DEATHS IN THE SERVICES.

Lieut.-Colonel Allen Andrew Lyle, R.A.M.C. (retired), died at Douglas, Isle of Man, on January 9th, aged 67. He was born at Belfast and educated in Dublin, taking the L.R.C.S.I. and L.K.Q.C.P. in 1876. He entered the army as surgeon in 1873, became lieutenant-colonel after twenty years' service, and retired on August 9th, 1898. After retirement he was employed for some time at Aldershot, and also served in the war of 1914-18, from June 7th, 1915.

Liam Napier Keefer, Bengal Medical Service, died on December 27th, 1922, aged 73. He was born in Ontario, and graduated B.A. Toronto in 1874, and M.D. and C.M. McGill in 1869. He took the L.R.C.S. Edin. and the L.S.A. in the same year, and entered the I.M.S. as assistant surgeon in 1869. He became surgeon-major after twelve years' service, and retired in 1889. Most of his service was passed in military employment; he was for many years medical officer of the 13th (Duke of Connaught's) Bengal Lancers (Watson's Horse). During the last five years of his service he held the post of chief medical officer of the Andaman Islands. He served on the North-East Frontier of India in the Lushai expedition of 1871-72 (medal); on the North-West Frontier in the Jowaki campaign of 1877-78 (clasp); in the Afghan war of 1878-80, capture of Ali Masjid, Laghman Valley and Zaimukht expeditions, capture of Zawa (mentioned in dispatches, medal with clasp); and in Egypt, 1882, action at Kassassin, battle of Tel-el-Kebir (medal with clasp). Khedive's bronze star, and Order of the Osmanieh (4th class). During the recent war he gave a very large donation to the Red Cross.

## Medical News.

THE Postmaster-General asks us again to call the attention of medical practitioners to the regulations under which "deleterious liquids or substances," including pathological specimens, may be sent through the post, as packets of the kind found not properly packed are regarded as prohibited articles and are destroyed. Any such liquid or substance must be sent by letter post, not parcel post; it must be enclosed in a receptacle, hermetically sealed or otherwise securely closed, which receptacle must itself be placed in a strong wooden, leather, or metal case in such a way that it cannot shift, and with a sufficient quantity of some absorbent material (such as sawdust or cotton-wool) so packed about it to prevent leakage from the package in the event of damage to the receptacle. The package so made up must be conspicuously marked "Fragile, with care," and bear the words "Pathological specimen." A person who sends such liquid or substance contrary to these regulations is liable to prosecution.

A SPECIAL post-graduate course of systematic lectures and clinical demonstrations will be given at the National Hospital for Diseases of the Heart, Westmoreland Street, W.1, on Thursdays, at 5.30 p.m., commencing on February 15th and terminating on March 29th. Further particulars can be obtained on application to the dean at the hospital.

BEFORE the National Assembly of the Church of England brought its session to an end last week it adopted a proposal by the Bishop of London to appoint an advisory committee to consider social and industrial matters in which moral issues are involved. It would, in particular, watch bills introduced into Parliament and call conferences of persons interested in social and industrial problems. A proposal to employ a paid secretary was withdrawn.

AT the invitation of the Mayor and municipality, the Royal Institute of Public Health will hold its next annual congress in Scarborough from May 16th to 21st, 1923. The Congress will be conducted in the following five sections: (1) State Medicine and Municipal Hygiene; President, Sir William Middlebrook, late Lord Mayor of Leeds. (2) Naval, Military, Air, and Tropical Diseases; President, Lieut.-General Sir Arthur Sloggett, K.C.B., late D.G.M.S., British Armies in France. (3) Bacteriology and Bio-Chemistry; President, Dr. F. W. Twort, Superintendent, Brown Institute, University of London. (4) Women and the Public Health; President, Lady Dorothy Wood, President of the Yorkshire Federation for Maternity and Child Welfare. (5) Industrial Hygiene; President, Sir Lynden Macassey, K.B.E., Governor of the London School of Economics, University of London.

CIRCULARS of inquiry as to the accuracy of their addresses were sent on February 2nd to all persons whose names appeared in the printed *Dentists Register* for 1922—that is to say, to all persons registered before the passing of the Dentists Act, 1921. Any person coming within the above category who does not receive an inquiry in course of post should communicate with the Registrar of the Dental Board, 44, Hallam Street, W.1, without delay, in order that there may be no risk of the erasure of his name under Section 12 (3) of the Dentists Act, 1878.

A DISCUSSION on the detection and estimation of small quantities of arsenic was held recently at Nottingham, at a joint meeting of the Society of Public Analysts and the Nottingham Section of the Society of Chemical Industry. Mr. A. Chaston Chapman, F.R.S., described his experience during the last twenty-five years with the zinc-acid process, and gave an outline of his procedure, more particularly in the use of cadmium to render the zinc sensitive. Mr. Wilkie, secretary of the Nottingham Section, demonstrated the use of his electrolytic method of estimating arsenic, in which the reversibility of the reaction was prevented. Dr. Monier-Williams showed an electrolytic Marsh apparatus modified from that in use in the Government Laboratory. Major Trotman expressed the opinion that the preliminary treatment of the material was the crucial point of the estimation. He suggested that a conference should be called to discuss the standardization of methods of estimating arsenic.

DR. A. V. HILL, professor of physiology in the University of Manchester, will deliver the Friday evening discourse at the Royal Institution, 21, Albemarle Street, W.1, on February 16th, at 9 p.m., the subject being muscular exercise.

THE Ministry of Health has issued a revised list of the treatment centres for venereal diseases approved by the Ministry under Article III of the Public Health (Venereal Diseases) Regulations, 1916. Information is also given as to the days and hours of the out-patient clinics, and for the irrigation of cases of gonorrhoea during the intervals between the clinics.

WE announced a year ago that the Conjoint Board of Scientific Studies had arranged to issue an alphabetical list of titles of periodical publications containing the results of original research, together with indications of the libraries in London, Oxford, Cambridge, Aberystwyth, Edinburgh, and Dublin, in which they are filed. The Carnegie Trust has given £1,000 to defray the cost of including a larger number of libraries. It is stated that over 300 copies have already been subscribed for at two guineas each.

THE Departmental Committee on the Taxation and Regulation of Vehicles appointed by the Ministry of Transport held its first meeting on January 26th. It heard evidence from Sir Arthur Stanley, chairman of the Royal Automobile Club, with regard to the proposal that motor taxation should take the form of a flat-rate duty on motor spirit. The so-called private motor had, he said, become very largely a utility or business vehicle. Evidence was given at this and subsequent sittings on behalf of motor manufacturers and traders to the effect that the present system of taxation had a prejudicial effect on the design of British motors and hampered trade.

THE annual dinner of the Hunterian Society of London will be held on Tuesday next. Particulars can be obtained from Mr. A. E. Mortimer Woolf, F.R.C.S., 81, Wimpole Street, W.1.

THE Chairman of the Executive Committee of the British Red Cross Society, 19, Berkeley Street, London, W.1, in making an appeal for subscriptions to enable the Society to cope with the position in the Near East, states that the Greek Government cannot meet the pressing demands upon it. The refugees in Greece include thousands of British subjects from Asia Minor and Thrace. From Lady Rumbold's Hospital, already established at Dedeagatch in Western Thrace, with 300 beds, assistance could be sent to the villages in the surrounding country, but at least three clearing hospitals of 100 beds each are, it is said, urgently needed in Western Thrace.

WE are informed that we were under a misapprehension in stating that the system by which medical publishers send out books on approval is new to this country; in particular we learn that Messrs. H. K. Lewis and Co., of Gower Street, carry on the system not only in respect of their own publications, but of the works of any publisher.

IN view of the withdrawal of overseas contributions the Imperial Institute is in financial difficulties, and the Secretary of State for the Colonies has appointed a committee to consider what functions carried out by the Institute are essential, and whether these should be continued by it or attached elsewhere.

A PAPER was read recently before the Royal Society of Arts by Mr. T. H. Fairbrother, a chemist on the staff of the British Dyestuffs Corporation, and Dr. Arnold Renshaw of Manchester, on the relation between chemical constitution and antiseptic action in the coal-tar dyes. As a general rule, dyes which show any marked antiseptic action contain one or more amido groups in the molecule. The physical state of a substance has probably much to do with its power to destroy organisms or interfere with their growth. If a dye-stuff has a colloidal nature in solution it is not likely to be an active antiseptic. While antiseptic action cannot be predicted from chemical constitution alone, absence of antiseptic action can be so predicted. A series of aniline dye-stuffs have been investigated for their action on certain common bacteria and protozoa (the latter generally paramoecia, isolated from sewage). The dyes which had the greatest action on paramoecia were Nile blue, Meldola blue, auramine O, ethyl violet, magenta acetate, malachite green oxalate, and certain new violet dyes. Paramoecia forms were affected at once by these dyes at a dilution of 1:20,000. With Meldola blue D—a new preparation of Meldola blue with zinc chloride—immediate death occurred with a dilution of 1:80,000, and within two and a half hours with a dilution of 1:160,000. Neo-salvarsan solutions, in dilutions of 1:200, fail to kill paramoecia in two hours. Of the dyes mentioned auramine O, ethyl violet, malachite green oxalate, and magenta acetate have great bactericidal properties also, but oxazine dyes act more intensely upon protozoa than upon bacteria. Two of the most active dyes—auramine and Nile blue—were tried in varying dilutions upon trypanosomes freshly obtained by bleeding an infected mouse, and within fifteen minutes a dilution of 1:20,000 of either of these dyes destroyed all the trypanosomes in the film, whereas control films under the same conditions showed great activity at the end of thirty minutes. Experiments on animals are held to make it probable that auramine might be injected intravenously in trypanosomiasis without any untoward result. Answering a point raised in a brief discussion, Mr. Fairbrother said that, though certain dyes stained the protoplasm of the organism, the staining did not appear to have any great antiseptic significance.

IN response to an invitation from the President of the Rockefeller Foundation, a commission has been appointed by the Japanese Minister of Education to visit the United States next March as guests of the Foundation for the purpose of studying American and Canadian medical institutions and methods. The six members of the commission are Dr. Kinnosuke Miura, professor of medicine, Tokyo Imperial University; Dr. Sahachiro Hata, professor of medicine, Keio University, and director of the Kitasato Institute; Dr. Ketsusuke Miyairi, dean of the medical college, Imperial University of Kyushu; Dr. Mataro Nagayo, professor of pathology and pathological anatomy, Tokyo Imperial University; Dr. Akira Fujinami, professor of pathology and pathological anatomy, Kyoto Imperial University; and Dr. Yoshihiro Takegi, chief surgeon and professor of surgery in the Tokyo Charity Hospital and Medical College. The leading hospital and research centres of North America will be visited, and attention will be paid by the commission to public health and hospital organization and administration, as well as to medical research.

A PORTRAIT of Dr. C. J. Sells, who for forty-six years and a half served as medical officer of the Guildford Poor Law Institution, has been hung in the board room of the Guildford Guardians in appreciation of his valuable services. At the unveiling ceremony on January 27th a replica of the portrait was presented to Mrs. Sells.

THE price of Sir Archdall Reid's book, *Prevention of Venereal Disease* (Heinemann), has been reduced to 7s. 6d. net.

IT is now possible to travel in comfort from the Libyan border of Tunis to the Atlantic shores of Morocco. During the war the French Government constructed a network of splendid roads, particularly in Morocco, and since the war the Compagnie Générale Transatlantique has put motor cars upon them and established twenty-two hotels. Full particulars of these tours, and also with regard to the French Riviera, can be obtained from the Office Français du Tourisme, 56, Haymarket, London, S.W.1.

DR. ROUX, director of the Pasteur Institute of Paris, has received the distinction of the Grand Cross of the Royal Order of the Dannebrog.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

Correspondents who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

Authors desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, Aitology, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate, Westrand, London; telephone, 430, Gerrard.
3. MEDICAL SECRETARY, M. ... London; telephone, 2630, Gerrard. The address of the British Medical Association is 16, South Molton Street, London; telephone, 4737, Dublin, and of the Scottish Office, C. Rutland Square, Edinburgh (telegrams: Associate, Edinburgh; telephone, 4261, Central).

## QUERIES AND ANSWERS.

### INCOME TAX.

"M. D." gives particulars of the statement he sent in for assessment purposes.

We think that the root of the difficulty he finds in coming to some arrangement with the local inspector lies in the fact that the major items in his statement of earnings appear to have been estimated instead of having been taken from actual records of receipts. Out of the total gross earnings of £489, £200 is included for dispensary and £150 for private practice, and the claim for expenses of motor, chauffeur, and maid is put at an all-over figure of £350. "M. D." has evidently been placed in circumstances in which the keeping of proper records is almost impossible, but if he cannot produce more detailed evidence of his earnings than the above figures he is at a serious disadvantage in contesting the assessment. We advise "M. D." to see the inspector—or depute a friend or agent to do so—give him what

facts he can, and endeavour to come to some amicable arrangement of the whole matter. We have no doubt that if the facts as to "M. D.'s" illness are explained by letter the inspector will arrange for the matter to remain in abeyance for the present.

## LETTERS, NOTES, ETC.

### BLOOD UREA.

MR. A. BASIL ROOKE, F.R.C.S. (Bournemouth), writes: The following statement appears in Sir John Thomson-Walker's address on "Some problems of prostatectomy" published in your issue of January 27th: "The figures given as normal for the blood urea—namely, 20 to 25 per cent.—are too low in dealing with old men, and a blood urea of 40 to 50 per cent. may be present without indicating serious impairment of the renal function. I recently operated on a patient whose blood urea was 58 per cent., and who had been refused a single-stage prostatectomy on this account. The patient was in other respects a healthy man, and I disregarded the high blood urea. Recovery from the operation was uneventful." W. F. Braasch states: "It is generally recognized that an estimation of 40 mg. of urea nitrogen for each 100 c.c.m. of blood would indicate a guarded prognosis, and when it reaches more than 100 mg. the prognosis is very grave" (*Diagnosis of Surgical Lesions of the Kidney*, Mayo Clinic, 1919). The practice of recording the blood urea sometimes as a percentage and at others as milligrams in 100 c.c.m. facilitates such clerical errors as those in Sir John Thomson-Walker's paper, and is a source of much confusion. In the ... the result is expressed as a percentage of the same terminology for blood the position of the decimal point.

We referred this note to Sir John Thomson-Walker, who writes: I am obliged to Mr. A. Basil Rook for pointing out the clerical errors which have occurred in transcribing the figures of the blood urea in my address on prostatectomy. The figures should have been expressed in milligrams per 100 c.c.m. Without doubt the use of two methods of record promotes confusion, and it would be safer to use one common method. Whether the urea should be expressed in terms of percentage or in milligrams per 100 c.c.m. must lie with the biochemist rather than the surgeon.

### THE NATIONAL MILK CONFERENCE.

AN account of the National Milk Conference held at the Guildhall, London, last October, under the presidency of Viscount Astor, appeared in our columns at the time. The full report of the proceedings has now been published, in a paper-covered volume of some 220 pages, by the National Clean Milk Society, the conveners of the Conference (3, Bedford Square, W.C.1; 3s. post free). It will prove of interest and value to all who take a practical interest in the problems connected with milk and dairies.

### WINTER IN ITALY.

WE published a short time ago (January 20th, p. 116) an article on the opportunities Italy afforded to winter visitors. The Italian State Tourist Department, 12, Waterloo Place, London, S.W.1, has issued an illustrated pamphlet by Major W. Stormont, F.R.G.S., giving information on all the places mentioned in our article, and also a note on winter sport centres, such as Cortina d'Ampezzo. The price of the pamphlet is 6d., by post 1s.

### MERCURY-VAPOUR LAMPS.

MESSRS. WATSON AND SONS (Parker Street, Kingsway, London, W.C.2) have issued a bulletin on the mercury-vapour arc, with descriptions of the mercury-vapour lamp made by them.

### A CORRECTION.

THE price of the Dodge Brothers' coupé was given in our last issue as £375, whereas the figure should be £395.

### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 31, 34, 35, and 37 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 32, 33, and 34.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 47.

## SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	0 9 0
Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Half single column	...	...	3 15 0
Half page	...	...	10 0 0
Whole page	...	...	20 0 0

An average line contains six words. All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive post restante letters addressed either in initials or numbers.

## The Hunterian Oration

ON

JOHN HUNTER (1728-1793): HIS AFFAIRS,  
HABITS, AND OPINIONS.DELIVERED AT THE ROYAL COLLEGE OF SURGEONS,  
FEBRUARY 14TH, 1923,

BY

SIR JOHN BLAND-SUTTON, F.R.C.S.,  
CONSULTING SURGEON, MIDDLESEX HOSPITAL.

My knowledge of John Hunter began in a curious way. In my ninth year I was taken to his famous house at Earl's Court and shown the den in the garden where he kept wild beasts in order to study them. Being fond of animals, this made a deep impression on my mind. In the simple religious exercises of my childhood, the story of Adam and Eve, the first keepers of a zoological garden, and the famous exploits of Noah, collector and preserver of wild animals, had great charm for me. Some years later the visit came vividly to my mind on finding a dilapidated copy of Otley's *Life of Hunter*, which I read eagerly. Ever since I have been deeply interested in all that relates to this extraordinary man, and the preparation of this Oration has been to me a delightful and engrossing occupation.

## LONG CALDERWOOD (1728-1748).

John Hunter was born at the farmhouse Long Calderwood, near Glasgow. The house bears a tablet to the effect that he was born February 13th, 1728. In his lifetime the birthday was kept on February 14th, and this College drinks to his

FIG. 1.—The nerves on the nasal septum. (Hunterian.)

memory in "Solemn Silence" on the 14th. Like myself he was probably born so late at night that in the hurry-scurry the midwife failed to notice whether he appeared just before or shortly after the clock struck twelve.

John, or Jockie, as he was called at home, the youngest of a family of ten, petted by his mother (his father died in 1741, aged 78), disliked school and hated books. He preferred to lead an out-of-doors life, looking after nests, insects, and animals, whilst his brothers got the same education as country gentlemen.

At the age of 17 he spent some months with a brother-in-law, a timber merchant and carpenter in Glasgow, and we can well believe he tried his hand with tools; his mother noticed that the "lad showed neatness of hands and quickness of perception in anything that regarded mechanism." What inquisitive boy has not meddled with awls and gimlets, mallets and chisels, hammers and nails, saws and planes?

Sharp boys can learn much that is useful in workshops, and a training in joinery teaches neatness and precision. Looking back it is instructive to consider how the farm life fitted John Hunter for his subsequent career. The practical surgeon is a craftsman: Greek and Latin are useful to him for polish, but think of the natural knowledge a smart boy can collect on a farm about sowing, sprouting, and the

ripening of crops; the breeding of animals, gelding of colts, spaying of pigs, caponizing of cocks, fattening and slaughtering of animals for food; farriery—shoeing and doctoring of horses; the wild life in ponds and ditches, fields and hedgerows, trees and heather. In the village he can watch the wheelwright, smith, tinker, glazier, cobbler, and cooper, all experts with simple tools.

Practical knowledge of this kind was useful in that state of life unto which William Hunter called his youngest brother.

## HUMAN ANATOMY (1748-1760).

At the age of 20 John Hunter came to London with the object of assisting his brother William, who had a school of anatomy at the back of his house in Covent Garden. John showed unusual skill in dissecting, worked hard, liked the companionship of men of his own age, and was fond of the theatre. There can be no doubt that he was an example of the medical student skilfully described by Dickens in *Pickwick Papers* (1836) and Albert Smith in *Punch* (1841).

Human anatomy appealed to this uncouth Scot, and William Hunter, a cultured man, moulded John's character and "bred him to anatomy" in its widest significance, with astonishing results.

In the summer of 1754 Hunter was busy studying the routes by which the branches of the fifth nerve leave the

FIG. 2.—Section of a rabbit's nose exposing Jacobson's organ. (Klejo.)

skull—a fascinating exercise. He unravelled the branches of the olfactory nerve, traced the course of the naso-palatine nerve, and the rambling nerve known as the nasal branch of the ophthalmic division of the fifth. A specimen (Fig. 1) he dissected to show these nerves exists in the museum, in excellent condition.

Hunter's attention was arrested by the uniformity in the course and distribution of nerves. Even now, few grasp the problem presented by the branches of the olfactory nerve which run down the anterior border of the nasal septum. In 1811 Jacobson, a surgeon in the Danish army, discovered a curious organ lodged in a scroll of cartilage situated on the anterior part of the base of the nasal septum (Fig. 2).

Jacobson's organ—a vestige in man, ape, and whales—is well developed in many mammals. Little is known of its function, but the specialized cells lining its cavity receive the olfactory twigs detected by Hunter. Jacobson's organ is well developed in mammals with long snouts, especially insectivora that find food at dusk; rodents whose young are born blind and live in deep burrows; and kangaroos, whose young must find their way into, and pass many weeks snugly ensconced in, the mother's warm pouch.

The prime service of olfaction is the quest for food, and is of first-rate importance to mammals born blind—it enables

them to find the teats of the mother. The vomero-nasal is subsidiary to the olfactory organ.

The morphology of the canals and foramina by which the cranial nerves leave the skull has always fascinated me, and many delightful hours of my life have been spent in unravelling the secrets connected with their methods of exit, re-entrance, and final escape from the skull. The study interested Hunter, apart from its morphological aspect. In his day vestiges were merely anatomical curiosities. How much greater the interest for us to unravel these curious courses in the light of man's evolution!

For Hunter morphology was a gleam in the intellectual sky. We revel in the sunshine; Morphology has become the Soul of Anatomy.

Many regard the dissection of the human body as a repulsive exercise. Many begin to dissect with disgust, but overcome the distaste and continue the study because it fits them for the medical profession. Some

FIG. 3.—Segment of an eel showing the ovary. The brittle marks the end of the rectum and the abdominal pore. (Hunterian.)

who have found difficulty in retaining or appreciating the facts of anatomy have shone in other professions. On the other hand, men unable to grasp mathematics or the principles of physics have become proficient anatomists. In a few instances men working at a humdrum calling turned to anatomy more or less accidentally and pursued it with zeal and success.

It is easy to understand that the unschooled, apparently idle, Jock Hunter, when introduced to the dissecting-room, became interested in the structure of the human body and found it an absorbing study.

*Verily the gunpowder of genius is stored in many minds, but—it needs a match!*

#### BELLEISLE AND MARINE ZOOLOGY (1760-1762).

Hunter during the first period of his life in London (1748-1760) acquired a practical knowledge of human anatomy, but this was mainly a study for the winter months. During the summer he studied surgery, following Cheselden for a season, also Pott, but St. George's Hospital offered better chances, and he joined as surgeon's pupil, and later had the good fortune to serve as house-surgeon for two years—an invaluable experience.

Whilst engaged in the routine of dissecting and teaching he developed a taste for comparative anatomy, which became an absorbing passion, enhanced by a change of locality. In the spring of 1759 he had some lung trouble, which made it necessary for him to seek change of climate. In 1760 a force was sent from England to take Belleisle, near the mouth of the Loire. Hunter applied for an appointment with the expedition and served as staff surgeon. This gave him the chance of obtaining practical knowledge of gunshot wounds.

Belleisle, well named, is a pretty island, now almost treeless. It is a plateau of 33 square miles about 130 feet above sea-level; here and there slopes give access to beautiful tracts of white sand. The coast has many grottoes. The most remarkable is La Grotte de l'Apothicaire, a sanctuary for sea birds; their nests in rows on ledges of the rocks are supposed to resemble bottles on the shelves of a pharmacy.

I spent a week on this lovely island and realized what a change it proved for a man from London ardently pursuing

comparative anatomy, a country new to him in flora and fauna. He took advantage of it by observing, collecting, dissecting, experimenting, preparing and preserving specimens. Hunter had no knowledge of marine zoology until he landed on this island, which afforded him access to barnacles, sea squirts, sea nettles, sea stars, sea anemones, sea cucumbers, sea urchins, huge spider crabs, tunny fish, and conger eels.

While studying and dissecting these animals the idea came into his mind that living things could be arranged in a physiological series, but he was puzzled to ascertain the use of strange organs he met with in marine invertebrata.

Like Cuvier he had to rely on naked-eye dissection, but dissection, however skilful, does not enable anatomists to determine minute structure of soft organs, which is the key to function. These difficulties are shown in Hunter's studies of the reproductive organs of eels. He truly observes, "the production of animals out of themselves excites wonder and curiosity." The precise manner in which it is carried out has required centuries of observation for its demonstration. The eggs of flies, butterflies, fishes, frogs, turtle, crocodiles, snakes, and birds appeal to the simplest mind.

It was difficult to prove that mammals came from eggs, for their small eggs require a microscope to make them visible. This is true of mice and men.

In London he got eels every month of the year from a fishmonger and examined the parts he expected to be the ovary with a magnifier, but without result. In the summer of 1761 there was a vast number of conger eels in the sea around Belleisle; he dissected many and satisfied himself that the ruffle-like organs he regarded as ovaries in the common eel were indeed ovaries (Fig. 3), but he did not solve the mystery of the propagation of eels.

In 1896 Grassi discovered that eels need salt water for the development of their reproductive organs, and the deep

FIG. 4.—Drawing showing the change from a yellow eel with thick lips, small eyes, and compact fin, into the large-eyed silvery eel which migrates to the ocean, where it becomes mature, spawns, and dies. (From models in the Natural History Museum.)

sea is their spawning place. In autumn they migrate to the sea and the dull yellow of their skin changes to silvery glitter; the eyes enlarge, the pectoral fins become black and change in shape, and the ova ripen (Fig 4). Mature eels cease to feed, and after spawning die.

Recently hatched eels, called leptocephali, are as transparent as glass, and the eyes shine through the water like black beads. When about 7 cm. long, leptocephali cease to

feed and change into elvers, which in spring find their way up the rivers in enormous numbers and in fresh water change into eels. These in their turn descend the rivers, seek the depths of the sea, where, decked in glorious sheen, they spawn and die.

Although Hunter did not get on well with his senior colleagues at Belleisle, he was comfortable on his pay, and enjoyed the opportunities for studying natural history, but in 1762 a British expedition to Portugal was the topic of conversation; he was keen to go, and his brother William helped him with the authorities in London to do so.

#### PORTUGAL AND GEOLOGY (1762-1763).

One of the last episodes of the seven years' war was an attempt on the part of France and Spain to invade Portugal. The French and Spanish forces were collected at Ciudad Rodrigo with the object of advancing on Lisbon.

England decided to support Portugal, and sent an expeditionary force of 7,000 men. The British and Portuguese troops, under the command of Count Schanburg-Lippe, an able officer trained in the school of Frederick the Great, assembled on the banks of the Tagus near the Spanish border. The outstanding feature of this almost forgotten campaign was the use for the first time of light cavalry, which General John Burgoyne was instrumental in introducing into the British Army. Under Burgoyne the cavalry rendered distinguished service at Valencia d'Alcantara, and in some sharp fighting at Villa Velha. The campaign was concluded by the peace of Paris 1763. Mr. Robert Boyne Home was the surgeon attached to the regiment of light horse.

John Hunter, transferred from Belleisle to Portugal, was in charge of a hospital; he landed at Lisbon in July, 1762, and in November was at Portalegre, near the Spanish frontier, 140 miles from Lisbon. General headquarters was at Estremoz, thirty miles south of Portalegre, on the direct road to Lisbon. Little is known of his doings in Portugal, and it has been supposed he made additional observations on gunshot wounds; for this there was not much opportunity, but with a force of 7,000 men there would be accidents and sickness incidental to a campaign in a foreign country.

It is certain that in Portugal Hunter made observations of natural history and collected specimens, some of which are preserved in the museum, but the most important gain was an inspiration to study geology. The hill on which Portalegre is built belongs to a remarkable plateau called Alentejo (spelt Alentejo in 1763). In an extraordinary tract published about fifty years after Hunter's death, under the title *Observations and Reflections on Geology*, he refers to the extensive plateau called Alentejo, which shows evident signs of its surface being covered by the sea, and to the enormous heaps of granite so frequent on the plain. The tract not only contains remarkable observations on geology but some ideas on the distribution of animals in relation to the antiquity of the world inconsistent with the creation as described in Genesis. He abstained from publishing them on the advice of friends.

Recently I visited Portalegre, the Alentejo, and the sur-

rounding country, and satisfied myself that Hunter while living on the plain had many inducements to study botany as well as geology, for he was among a subtropical flora, and at Lisbon had excellent opportunities for collecting specimens and adding to the knowledge of marine zoology he had acquired at Belleisle.

Hunter's domestic life was influenced in an important manner by the affairs of Portugal, for Home, surgeon to Burgoyne's regiment of light horse, became his friend. Returning to England, he got engaged to Home's daughter Anne. It was a long engagement, for they were not married till 1771. Mrs. Hunter's younger brother Everard became Hunter's house-pupil, then his assistant, and finally executor. Sir Everard Home and Matthew Baillie founded the Hunterian oration in 1813, and Everard Home was the first orator (1814).

#### EARL'S COURT.

On the conclusion of peace Hunter returned to London, a staff surgeon and deputy purveyor on half-pay. He took a house in Golden Square and started to practise. His half-pay, probably half a guinea a day, helped to pay the rent. He opened a room for dissecting, made teaching preparations, and, while waiting for patients, like many of us taught human anatomy for capital and comparative anatomy for interest. The classes were neither large nor lucrative, for he was not a good lecturer.

In 1765 he bought the lease of three pieces of land at Earl's Court, built a house, established a small menagerie, and made observations and experiments—

On gizzards of gulls,  
hawks and owls,  
The heat of lizards, spurs  
of fowls;  
Bones of pigs, air sacs  
of eagles,  
Moaning dingoes, barking  
beagles;  
Sleek opossums, prickly  
hedgehogs,  
Buffaloes, dormice,  
wolves and dogs.

Leopards and jackals  
lived in the den; stallions,  
sheep, goats, and rams  
occupied the stables. A

mulberry-tree furnished leaves for the silkworms, and St. John's wort supplied pollen for the bees. There was a pond for ducks and geese which laid eggs for the table and for embryological study.

Hunter made observation hives for the bees, discovered that their wax was a secretion, and left some excellent notes on the relation of vegetables to animal fat. With the aid of Ramsden's delicate thermometers he discovered the significance of the terms "hot-blooded" and "cold-blooded" animals. He would have been astonished to learn that muscular action is the main source of animal heat. Hunter failed to grasp the importance of measuring the temperature of the body for clinical purposes. Indeed, the value of the clinical thermometer was not appreciated until the middle of the nineteenth century.

Earl's Court remained a bachelor's residence for seven years. In 1771 John Hunter, aged 43, married Anne Home, aged 29, a charming, amiable, and accomplished spinster, who in due course added to the physiologist's paradise the most delightful of all objects of natural history—children. Mrs. Hunter had a brother, Robert Home, an artist, who painted a portrait of Hunter which eventually came into the possession of the Royal Society. In 1787 Hunter read a

FIG. 5.—John Hunter, by Robert Home. The dog is supposed to be the offspring of a half-bred wolf bitch and an English mastiff.

paper before that society on some observations "tending to show that the wolf, jackal, and dog are all of the same species." The odd dog in the picture is supposed to be the offspring of a half-bred wolf bitch and an English mastiff. The dog died in 1782. The portrait represents Hunter about the age of 45. He describes himself at this period in a letter to James Baillie, his brother-in-law, as "one of the happyst men living" (1775), in spite of the fact that he had to raise money on the Earl's Court property, a fact concerning which Dr. G. C. Peachey has found unimpeachable documentary evidence.

Hunter was a resident at Earl's Court for thirty years. In 1877 the Royal College of Surgeons, and a few friends, placed a window to his memory in the north transept of St. Mary Abbot's Church, Kensington. One of the principal lights represents St. Paul in the island of Melita casting a viper off his hand.

#### THE MUSEUM.

Nothing is known of the time Hunter began to collect specimens with the definite object of establishing a comprehensive museum of comparative anatomy. The Museum owes its origin to the peculiar conditions under which medical education was carried on in London in the eighteenth century. Schools of anatomy were private ventures. It was necessary for a surgeon who owned and managed a school to illustrate his lectures with skilfully prepared specimens. Such preparations are more useful than diagrams, wax models, or drawings on blackboards, even when made with skull and coloured chalk.

Hunter made many preparations for his brother, and some exist in the Hunterian Museum at Glasgow, but when he returned to London in 1763 he brought with him specimens of natural history from Belleisle and Portugal, and they formed the nucleus of the comparative anatomy series. It is a fair inference that such specimens were collected for teaching purposes connected with his lectures, but the collection grew until it became a museum that could be regarded as a discourse on the human body in relation to the animal kingdom. Gradually its founder's ideas expanded, and he conceived that it would be an ample illustration of life exhibited in the vast chain of organized beings, living and extinct, by a display of the various organs in which the functions of life are carried on.

In 1783 the lease of the house (42, Jermyn Street) which he had acquired from his brother William expired. He then took premises in Leicester Square and built his famous Museum. Sir Joshua Reynolds lived in the square, and the two men subsequently helped each other to what artists jokingly call immortality—one as subject, the other as painter. When Baron Grant furnished Leicester Square and laid out the garden in 1874 a colossal bust of Hunter was placed in one corner and a bust of Reynolds in another.

Hunter's example in collecting specimens was contagious. Blizzard, Astley Cooper, Heavyside, and other surgeons formed museums, but the specimens are dispersed. The care entailed in the upkeep and supervision of such museums is very great. Hunter's collection nearly perished. His executors, Matthew Baillie and Everard Home, when struggling young practitioners, with sound judgement retained the services of William Clift, who preserved the specimens from decay by the judicious use of two gallons of spirit occasionally. He had no books, so he read and made extracts from Hunter's manuscripts. The transcripts were made from some of the notes afterwards destroyed by Everard Home. They were published as *Essays and Observations* by Owen (1861). For seven years Clift received seven shillings weekly and meekly as wages. In return for these services he was made first Conservator when the Government bought the collection and entrusted it to the College in 1800. The Museum contains in orderly array big and little of every living thing Hunter could obtain: shrimps and sharks, tits and ostriches, shrews and whales; of the human kind dwarfs and giants. Animals

now living on the earth were not enough—he must have fossil forms. When John White returned to England (1790) from New South Wales "the nondescript animals, Kangaroo, Tapua Roo, and Potoroo" were handed to Hunter for investigation. It is now so rich in specimens illustrating the anatomy of vertebrates, living or extinct, normal and abnormal, that no one who is prudent ventures to publish anything he thinks new without examining correlated specimens in the Museum. It abounds in surprises, and is in a sense an anatomical Valhalla.

#### PATHOLOGY.

Specimens illustrating "diseased action" were preserved in the museum. Pathology is a department of Biology. Hunter's ideas of many pathological processes were crude; without the aid of a compound microscope, section-cutting and staining methods, his knowledge of tumours was not above that of the farrier. Shepherds talk of corns, warts, blains, wens, and blemishes. The slaughterhouse supplied him with melanotic tumours from oxen, and from the knacker's yard he got similar things from horses. Graveyards yielded calcified fibroids and tumours of bones.

In Hunter's day, and for many years afterwards, pathological specimens were mainly spoils from the dead-house; to-day they are prizes from the operation theatre. The history of surgical progress during the last fifty years can be traced in the Museum catalogue. The hall in the Museum that enshrines Hunter's statue is a temple of pathology, admirably arranged and catalogued by Shattock. It should stimulate surgeons to study the science as well as practise the art of surgery.

#### EMBRYOLOGY.

Hunter's keen interest in monsters was not mere curiosity, but part of a great scheme for showing the phases of Life. The collection of Malformations in the Museum is the most comprehensive in the world. He was aware of the importance of a knowledge of the developmental stages of animals, and applied himself to study the chick. He studied geese because their embryos are bigger than those of fowls. He tried swans,

but could not get eggs enough. He tried to obtain ostrich eggs, but only got two in thirty years, and made nothing out of them. The flock of geese for embryological work was kept at Earl's Court for thirty years.

Although he obtained much first-hand knowledge from this work, and some excellent drawings, he discovered little of importance, but left among his notes, awkwardly expressed—for masters of science are rarely masters of style—

*Embryology indicates the steps by which the higher forms in a group of animals have been evolved from a lower.*

Thirty years after Hunter's death von Baer discovered the human ovum, and realized that embryology is the key to the knowledge of the human body.

Hunter collected books but read little. Probably he never read the *System of Philosophy* written by Lucretius, although both men reasoned on inexplicable things:

LUCRETIUS: "Before the horns of a calf appear and sprout, he butts when angry and pushes passionately. But the cubs of panthers and lions' whelps already fight with claws, and biting, when their teeth and claws are scarcely yet formed."

HUNTER: "A duckling runs into the water the moment it sees it. A hen with ducklings seeing them run into the water is unhappy."

"A duck with chickens tries to induce them to enter the water; they run about the bank."

In relation to these paragraphs it may be stated that incubators and serial sections aided by the most exquisite stains throw no light on instinct. Though dogs and pigs do not interbreed, maternal instinct may be so strong in a bitch that she will suckle a sow's orphans (Fig. 6).

*Pity is not an exclusive attribute of gods and men.*

FIG. 6.—Alsatian bitch, whose pups had died, suckling six little pigs. (*Veterinary Journal*, 1920.)

## FEATHER-THICKETS.

In March, 1778, Hunter requested Jenner, his former pupil and friend, to watch a blackbird's nest, and remove the nestlings one by one on different days and preserve them in spirits in order to show the manner in which their feathers grow. He wrote details of the way in which the birds were to be treated, and Jenner carried out the instructions admirably, and the preserved nestlings are in good condition to-day (Figs. 7 and 8).

Forty years after Hunter's death Owen found among the MSS., transcribed by the faithful Clift, some notes on the situation of feathers:

Although the feathers of birds appear to be an entire and uniform covering, they do not arise equally from every part of the body, but only from such parts of the skin as are least likely to be affected by the motion of the contiguous parts, such as the motion of the limbs. The feathers arise pretty equally on the head where there is no motion; and along the back, on the wings between joint and joint, and also on the thighs and legs, the whole making the bird a partial coat of mail. As they do not arise from every part of the skin equally they must be proportionally thickest where they do arise. The places of origin of feathers are very observable in a bird that has been plucked; but still more so in young birds just feathering, more especially of such as have little down, and of which the clump of feathers, from their colour, as in young blackbirds, present a great contrast with the skin. In the interstices of the clumps of feathers there are others disposed irregularly, but so sparingly as not to interfere with the motion of the part.

FIG. 7.—Callow blackbird. (Owen.)

FIG. 8.—Nestling blackbird. (Owen.)

Hunter named each feather-thicket according to its situation. In 1883 Nitzsch, unaware of these observations, published a study of the distribution of feathers. He called the thickets pterylae—feather forests—and the featherless spaces apteria.

The arrangement of feather-tracts (pterylosis) is now used as an aid in the classification of birds. Oken cast ridicule upon it; he could not refrain from laughter when he looked in Nitzsch's book, since the plates reminded him of plucked fowls in a poulterer's shop! We must admit that the idea is comic. Newton, referring to this joke, adds: It might as well be urged as an objection to the plates in many anatomical books that they call to mind a butcher's shop!

Hunter had his gibe at the systematists, for in his opinion natural historians are more pleased if they can class an animal than they would be if they could find any use such an animal would be to society.

The value of pterylosis in classification depends on the fact that feather-tracts, like beaks and feet, are modified by the habits of the bird.

These callow blackbirds are as instructive as a parable. They prove Hunter's skill as a museum expert. The contrast in colour—black and white—is excellent, and the skill shown in mounting them undeniable. They were prepared in 1788, and remained in obscurity until Owen found them nearly fifty years later.

Hunter had great power of observation, but lacked the gift of exposition. His discovery was like a lighted candle under a bushel. Half a century later Nitzsch detected the value of pterylosis and urged its importance in spite of ridicule. It is one thing to make a discovery, but it is another to make con-

temporaries accept it, or appreciate its value. It is as hard to establish a truth as to eradicate an error.

## THE HORSE.

Hunter studied the horse carefully as an anatomist and as a surgeon. It was natural that he should study an animal that can walk quickly, amble easily, trot gracefully, or gallop with exceeding swiftness on limbs

each of which ends in a modified toe, or finger, and in spite of many anomalies be so useful to man. He was thoroughly familiar with equine anatomy, the teeth especially; left a careful description of the curious guttural pouches connected with the pharyngeal ends of the Eustachian tubes, and discovered the con-

jugal ligament, which connects the heads of the ribs or opposite sides of the spine. This ligament, well developed in the seal (Fig. 9), is homologous with the thick transverse ligament that not only keeps the odontoid process of the axis in position, but excites curiosity in every student when he sees it for the first time.

Hunter helped to found the Royal Veterinary College (1791); he was a vice-president, and with Cline served on a committee that approved of the appointment of Vian St. Bel as the first professor of the College. Among the first operations performed by St. Bel was one for the removal of "two accessory feet which grew from the fetlocks of the two forelegs." Hunter assisted and gave him some useful and friendly hints.

St. Bel died in 1793 from glanders. His early and unexpected death led to some difficulty, and Hunter, in order to help in the emergency, arranged for the students to have admission to the lectures of the leading teachers in the hospitals. The names mentioned in this connexion were Dr.

Fordyce, Dr. Baillie, Cruickshanks, and Everard Home. The directors of the College sent Hunter a letter of thanks for this help, which he acknowledged in a letter from Leicester Square, October 2nd, 1793, exactly two weeks before he died. This letter long remained a treasured possession of that College but it has been lost.

Hunter's coach was drawn by a pair of bay stone horses. Jesse Foot, his detractor, saw these horses in Piccadilly returning from the funeral at St. Martin's Church. The circumstance recalled to his

mind Virgil's account of the war-horse Aethon, in the funeral procession of young Pallas, shedding tears!

## WHALES.

Whales are the biggest animals that exist or have existed on the earth, and their skeletons are the most impressive things in the Museum. Hunter recognized that whales are land mammals modified to live in the water. He dissected them when he got the opportunity and discovered their semicircular canal.

The organ of hearing in these huge mammals is modified in a remarkable manner. The pinna is absent; the meatus is narrow and, in some species, nearly obliterated. The tympanic is a shell of bone; the ossicles—malleus, incus, and stapes—are present. The tympanics are so loosely attached to the skull that when the bodies of whales decompose these bones

FIG. 9.—Conjugal ligament of a seal.

fall away. In the central Pacific detached tympanics, petrosals, and shark's teeth litter the floor of the ocean. Hunter studied the semicircular canals of fishes before he went to Belleisle, and it is reasonable to believe that the structure of the internal ear interested him for thirty years.

Lillie in 1910 and 1915 made some dissections of the internal ear of whales, and explains the vestigial character of the external auditory meatus by suggesting that whales hear through their nasal passage, which opens on the top of their heads. The nostrils collect the sound waves to be conducted through the blow-holes to the huge guttural pouches and the Eustachian tubes, thence to the tympanic bullae, which act as sounding boxes and transmit the sound waves to the chain of ossicles.

The shell-like tympanic probably intensifies the sound waves in the water. There is no doubt that whales rely on the sense of hearing, and appreciate the pulsations caused by waves striking rocks, or the approach of an enemy. These shell-shaped bones are often kept as curiosities. One of them here is seen in Fig. 10; it was used as a paper-weight by a lady of fashion, yet it collected sound waves that enabled a mighty whale to move through unfathomable waters with the same certainty that the compass enables mariners to guide ships across the trackless ocean.

Intrepid whalers who have watched whales in the solitary ocean regard them as timid and inoffensive, with large brown eyes and affectionate in disposition to their young. This character does not apply to the toothed whale. The killer whale has a large dorsal fin, and there has been much speculation in regard to its use. Herman Melville in *Moby Dick* states that the flukes of whales are tactile organs of great delicacy. I believe that the median fin of a killer is a tactile organ. On watching a killer rise to the surface, this dorsal fin is seen to rise like the periscope of a submarine (Fig. 11).

Captain Wild has described to me tricks of *Orca* worthy of a crocodile. It is not easy for a killer to seize a seal on the edge of the ice, but he swims under it, and rising suddenly, breaks off a piece with the object of dislodging the seal. If the seal retreats, crafty *Orca* follows the animal as it lumbers over the ice and breaks off successive pieces in his endeavours to seize the creature. In such tricks the dorsal fin may be a reliable tactile organ like the whiskers of cats and the feelers of catfishes. Killer whales have formidable teeth, insatiable appetites, hunt in packs like wolves, and attack the biggest whales.

When Hunter died in 1793, and for many years afterwards, his skeletons of whales were the only examples existing in a museum in England. Imagine the enthusiasm of a surgeon actively engaged in practice, finding time for dissecting such huge animals, mounting their skeletons and housing them!

#### OPOSSUMS AND KANGAROOS.

Hunter kept opossums at Earl's Court, and about 1790, when he was studying the marsupials which John White brought from New South Wales, he wrote: "There is something in the mode of propagation in the opossums that

deviates from all others." He kept many alive, "yet never could get them to breed."

The manner in which the foetus gets into the pouch, affords a simple explanation for opossums and kangaroos. Goerling of Perth, Australia, discovered in 1906 that when the embryo is extruded from the vagina it is blind, but the arms are well developed, the fingers furnished with claws, and it can open and close its hands like the paws of a cat. The foetus, which makes its way through the fur to the opening of the pouch, enters, finds a teat and fastens itself on with the powerful lips (Fig. 12).

The little wanderer travels through the mother's fur, moving the arms alternately as in swimming, and leaves a track in the fur which lasts some hours. In the pouch the little fellow finds protection, warmth, and nourishment, and remains there till the eyes are opened and it has donned a fur coat; then, as many have seen with delight at the Zoo, the little kangaroo looks over the rim of the pouch and gazes with curiosity on the world at large, and in a way that would

have amused John Hunter.\*

#### FOSSILS AND OWEN.

Belleisle and Portugal had much the same influence on Hunter as South America on Darwin, especially in relation to geology, and with unexpected consequences, for few suspected his interest in fossils, although they were often sent to him, especially by Jenner. The discovery of Hunter's collection of fossils is one of the romances of the Museum.

When Richard Owen in 1826 started practice as a surgeon near the College, Abernethy, concerned at the neglected condition of the Museum, induced his old pupil to assist in cataloguing it. In this way Owen became acquainted with Clift and the collection.

A few years later he married Clift's daughter, was gradually weaned from medical practice, and devoted himself to comparative anatomy. Whilst busy with the catalogue he unexpectedly found Hunter's store of fossils and displayed them in the Museum when it was rearranged in 1837. Startled by the number and variety of the specimens, he worked at them seriously. Nothing illustrates more thoroughly the parable of the sower than these fossils. Nearly all the seed sown by Hunter fell on stony ground, but

some fell and grew in Owen's fertile brain. He dissected animals to enable him to study fossils, and became essentially a palaeontologist, revelling in the reconstruction of extinct creatures.

The Museum contains reconstructed skeletons of huge ground sloths; the gigantic armadillo with "an osseous coat in compartments," and the huge bird, the moa, towering over all. Skeletons of sloths, armadillos, turtles, crocodiles, ostriches, and emus stand in rows to demonstrate the truth of Owen's deductions. When these skeletons were mounted "evolution" and "mammalian descent" had not become the stock phrases of zoological zealots.

\* O. G. Hartman discovered that the foetuses of the opossum (*Didelphis virginiana*) find their way into the mother's pouch in the same manner as the foetal kangaroo (*Anatomical Record*, 1920, xix, 25).

FIG. 10.—Tympanic of a whale.

FIG. 11.—*Orca gladiator*. Though killer whales are evil-looking, they glide gracefully through the sea, impelled by their powerful flukes.

To-day zoologists include extinct as well as living animals in their lists. Before Darwin classification was a mania, since Darwin zoologists persistently endeavour to bridge gaps.

FIG. 12.—Young kangaroo hanging on the teat by its lips. (Museum, Royal College of Surgeons.)

Hunter's fossils turned Owen's thoughts to palaeontology and led men to take an interest in animals, huge and weird, that once moved about the earth and then passed into the twilight and silence of the past.

#### THE ORATION.

A man who achieves greatness in any calling inspires others to follow his example. No man retains prominence unless he has impressed others to believe in him and magnify his name. Those who have been closely associated with a masterful teacher and speak well of him are often mockingly called disciples by his contemporaries. Many who during the lifetime of a great investigator or a reformer were detractors are often loudest in

appraising him when dead. When our friends are alive we hesitate to say much about them in their presence—except in after-dinner speeches. As soon as they are dead we are apt, in a paroxysm of sympathy, to overpraise their work. Hunter was in advance of his time; his contemporaries could not appreciate the value of his work, and some of his later admirers overrate it.

The delivery of the Oration is justified. It is necessary to remind men of their benefactors; even the holiest saints require to have their names preserved by shrines, chantries,

cathedrals, or festivals. Are there not saints' days in the calendar of every church—Protestant, Greek, or Roman?

Aesculapius had two famous sons: of these Machaon healed injuries, and Podalirius could recognize what was not visible to the eye and tended what could not be healed. They served with the army in the Trojan war.

Podalirius, returning from the war, was wrecked at Caria, Asia Minor. He had the good luck to cure a princess of falling sickness (probably hysteria), and in consequence acquired a great reputation. The Carians, after his death, built him a temple and paid him divine honours. This temple has long since disappeared, but his effigy survives on the College seal.

FIG. 13.

The essential work of Hunter's life was the useful specimens he prepared and left for successors. These specimens, safeguarded by faithful Clift, catalogued by sagacious Owen and Paget, and such able curators as Flower and Shattock, are now in the care of Keith, who lacks none of Hunter's enthusiasm but totally eclipses him in the art of exposition. The Museum was never in safer custody.

If I could believe the soul of man survives the dissolution of his body, I would believe the spirit of John Hunter haunts the galleries of this wonderful Museum, but I do believe his influence is a quickening spirit among surgeons to-day.

## THE PROPERTIES OF CERTAIN "COLLOIDAL" PREPARATIONS OF METALS.

BY

A. J. CLARK, M.C., M.D., F.R.C.P.

(From the Pharmacological Department, University College, London.)

CONSIDERABLE attention has been paid during the past decade to the therapeutic action of metals in the colloidal form. The clinical literature associated with this subject is very extensive, and the results recorded are extremely remarkable; indeed, a cursory survey of the subject leaves the impression that colloidal metals act as specific cures for every known disease. The full claims of colloidal therapy will be found in the works of Searle.<sup>1,2</sup> Unfortunately the quality of this literature does not correspond to its quantity. Dale,<sup>3</sup> in a review of Searle's book, points out that the claims made there regarding the action of colloidal metals violate most of the known laws of physiology. The *Journal of the American Medical Association*<sup>4</sup> criticized Searle's report as follows:

"In a style as bombastic and verbose as the usual house-organ write up, the report recklessly details all sorts of conditions, in which the so-called colloids—and particularly the Collosol brand—have been recommended, but derogatory findings are conspicuous by their absence."

An examination of the clinical literature further shows that the great mass of it is wholly uncritical, and that the few animal experiments and therapeutic observations which have been made with proper controls have mostly given negative results. Since the "scientific" literature on this subject is so uncritical, it is only natural that the manufacturers of colloidal preparations should have made rather startling therapeutic claims in advertising these preparations.

The author, at the invitation of the *BRITISH MEDICAL JOURNAL*, has investigated the properties of certain of the colloidal preparations advertised. The preparations investigated were certain of the collosols (The Crookes' Laboratories) and of the oscols (Messrs. Oppenheimer and Son, Ltd.). The preparations were bought in the open market, but care was taken to ensure that they had come recently from the manufacturers. The retail price of collosols varied from 2s. to 6s., and that of oscols from 2s. to 15s., a 4-oz. bottle.

### Chemico-physical Properties.

The preparations contain in most cases 1 in 2,000 of metal, together with 0.6 per cent. of sodium chloride, and from 0.5 per cent. to 5 per cent. of organic matter. The organic matter in collosols is in some cases stated to be arabinic acid derived from gum arabic, and in other cases to be glutaminic acid derived from gelatin; in the patent specifications peptones are said to be used as the suspending agent. The organic matter acts as a protective to the colloidal metal and keeps it in suspension. Ultrafiltration showed that the organic matter was partly in colloidal form and partly in true solution, for the greater part of it passed through collodion membranes, but a part of it was retained.

The chief point to be determined was whether all or any of the active principles in the various preparations were in true colloidal suspension. The following are the chief tests by which colloidal solutions are distinguished from true solutions:

1. *Ultramicroscopic Examination*.—The ultramicroscope shows colloidal solutions to be full of microns, which appear as bright points undergoing rapid Brownian movement.

2. *Tyndall's Beam*.—A beam of light passed through a colloidal solution illuminates its path, just as a beam of sunlight in a darkened room is visible when the air contains dust or smoke.

3. *Kataphoresis*.—An electric current passed through a colloidal solution contained in a U tube causes the solution to move towards one of the electrodes.

4. *Dialysis and Ultrafiltration*.—Colloidal particles do not pass through such membranes as parchment or collodion.

5. *Diffusion*.—Colloidal particles diffuse into water much more slowly than do molecules or ions. Colloidal particles do not diffuse into gelatin.

These tests can easily be applied to pure solutions of colloidal metals, but the presence of a considerable quantity of organic matter in the preparations tested made them much more difficult to test.

The manufacturers apparently rely upon ultramicroscopic examination for determining the state of suspension of the metal, for they emphasize in their advertisements that the preparations show Brownian movement under the ultramicroscope, and state that this is evidence of the colloidal nature of the preparations. The absence of particles on ultramicroscopic examination is evidence of the absence of colloidal

matter; on the other hand, most forms of colloidal matter will show visible particles under the ultramicroscope. For instance, the ultramicroscopic examination of soapy water shows an extremely brilliant picture of microns in active Brownian movement. The ultramicroscope cannot therefore give any reliable evidence as to whether metals mixed with an excess of organic matter are in a colloidal state, for the particles seen may be metallic or organic; evidence may be obtained that probably some of the metal is in colloidal form, but it is not possible under these conditions to estimate how much of the metal is in colloidal suspension.

Kataphoresis also is of little value as a test for the physical state of these solutions. The passage of an electric current through these solutions caused a movement of the solution towards the anode, but this may have been due to the colloidal organic matter present.

Dialysis through parchment thimbles was next tried. The solutions were placed in parchment thimbles and were dialysed for six days. The results are shown in Table I. This test showed that oscol ferrum and oscol argentum were true colloidal solutions, for none of these metals passed through the parchment. In all the other cases examined a considerable proportion of the metal passed through the parchment. This suggested doubts as to whether these preparations were colloidal, but the test is open to the objection that the solutions may have oxidized on exposure to the air.

Kütz<sup>1</sup> examined a preparation of colloidal arsenic and found that on exposure to the air free arsenious acid was liberated slowly; with a solution of 0.1 per cent. of arsenic in colloidal form, after three days' exposure to the air, 0.07 per cent. of free arsenious acid was liberated.

#### Ultrafiltration Experiments.

Since dialysis was inconclusive, ultrafiltration was employed. Collodion membranes were used. At first membranes were made from 7 per cent. collodion dissolved in equal parts of ether and alcohol, the membranes were made to fit Buchner funnels, and fluid was driven through under a pressure of two atmospheres. In later experiments collodion thimbles were made from 9 per cent. collodion in equal parts of ether and alcohol; the thimble was fixed to a rubber cork through which passed a glass tube, and a pressure of 100 c.cm. of water was used to drive the fluid through the thimble. In all cases the membranes employed were tested by filtering through them solutions of Congo red or haemoglobin, and only those membranes were used which retained 99 per cent. of these substances. About 5 c.cm. of fluid could be filtered in from one to three hours by these methods.

The colloidal preparations were tested by taking 20 c.cm. of the preparation, filtering through 10 c.cm., and then estimating the amount of metal in the filtrate and in the residue.

Iron preparations were estimated colorimetrically with ferricyanide. Arsenic and antimony were estimated gravimetrically by precipitating as the sulphide; in some cases arsenic was also estimated quantitatively by Marsh's test. Quinine was estimated by extracting the solution with chloroform and then estimating the residue obtained from the chloroform volumetrically by using Mayer's reagent as

described by Schmidt.<sup>5</sup> Silver was estimated volumetrically with cyanide solution. The results of these experiments are shown in Table I.

The results shown in Table I indicate that the whole of the metal present in oscol ferrum and oscol argentum is in a colloidal form, and that it does not pass into true solution on exposure to the air. Collosol antimonium and arsenicum and oscol arsenicum and stibium all appear to contain a mixture of colloidal and non-colloidal metal, but on exposure to the air the metal tends to pass into true solution. Very little of the quinine in collosol quinine appears to be in colloidal form, and no demonstrable quantity of the iron in collosol ferrum appears to be in colloidal form.

#### Diffusion Experiments.

Further experiments were made to measure the rate of diffusion into water. Tubes 27 cm. long, with a diameter of 6 mm., were closed at one end and filled with water; the tubes could be inverted without the water escaping. A solution of collosol was put in a small bottle, a tube was dipped into the solution, the bottle closed with a rubber ring, and then left to stand in a dark cellar for sixteen days. At the end of this period the metal content of the solution within and without the tube was estimated. This method is a rough one for measuring diffusion, but control experiments showed a well marked difference between colloidal and non-colloidal substances. The results are given in Table II, and it will be seen that with non-colloidal substances the concentration inside the tube is about one-seventh that of the outside solution, whereas with colloidal substances the concentration inside the tube is only about one-seventieth that of the outside solution.

Oscol ferrum behaved like a colloidal solution, but collosol ferrum and oscol iodine behaved like non-colloidal solutions. The iodine content of collosol iodine was so low that it was impossible to measure it exactly.

Further experiments were made to test the rate of diffusion of collosol ferrum and other iron solutions into gelatin. A tube was half filled with 10 per cent. gelatin, and 5 c.cm. of solution were poured on top of the gelatin; at the end of a week the distance the colour had diffused into the gelatin was noted, and the quantities of iron in the fluid and in the solution were estimated. These results are shown in Table III, and it will be seen that collosol ferrum diffused into the gelatin like a non-colloidal solution of iron.

The results of the diffusion experiments confirm the previously expressed opinion that the iron in collosol ferrum is in a non-colloidal form; they suggest also that the iodine in oscol iodum either is not in colloidal form or else passes into true solution very readily. Collosol iodine is advertised as "Crookes' Colloidal Iodine," and the statement is made—"Collosol iodine consists of a 0.2 per cent. colloidal solution of iodine." In a more recent publication<sup>2</sup> the statement is made—"Collosol iodine is a 0.05 per cent. colloidal solution of iodine suitably protected," and "Collosol Iodine Aqueous (Crookes)" is described as 1 in 500 (0.2 per cent.).

I have received the following report from the analyst selected by the BRITISH MEDICAL JOURNAL.

#### Analytical Report on Collosol Iodine.

I beg to report that I have analysed samples of collosol iodine, with results which show that it consists essentially of an aqueous solution of iodine with sodium chloride and gelatin.

The quantitative composition was found to vary in three bottles purchased on different occasions, but in no case was it found to exceed that which could be dissolved by a solution of simple character; the amount of iodine in the influence on its molecular nature or activity. Therefore the iodine is in no sense colloidal, nor indeed is there any colloidal quality in the preparation except the colloidal attribute of the dissolved gelatin.

The most notable effect of the gelatin in this composition is to reduce a part of the iodine to hydriodic acid, which becomes neutralized by the gelatin. The effect is visible as a loss of colour. Reference is made to the loss of colour in a separate label on the bottle, which states—

"If exposed to light collosol iodine becomes lighter in colour. The clinical efficiency is not affected, but for the sake of uniformity keep in a cool dark place."

TABLE I.

Preparation.	Amount of Active Principle stated to be present in—	Amount of Active Principle found on Analysis in—	Portion of Active Principle present which passed—	
			Collodion Membrane in Ultrafilter.	Parchment Dialysing Thimble (6 days' Dialysis).
	Per cent.	Per cent.	Per cent.	Per cent.
Collosol antimonium...	0.01	0.09	25	30
Collosol arsenicum ...	0.1-0.2	0.15	47	60
Collosol ferrum...	0.05	0.05	100	99
Collosol quinine ...	1.0	0.9	80	85
Oscol argentum...	0.05	0.05	nil	nil
Oscol arsenicum ...	0.05	0.05	25	80
Oscol ferrum ...	0.05	0.05	nil	nil
Oscol stibium ...	0.05	0.04	23	75

The following are the analyses:

I.					
Free iodine ...	...	...	...	...	0.021
Iodine as iodides ...	...	...	...	...	0.009
Sodium chloride ...	...	...	...	...	0.737
Gelatin ...	...	...	...	...	0.315
Water ...	...	...	...	...	99.918
100.000					
II.					
Free iodine ...	...	...	...	...	0.023
Iodine as iodides ...	...	...	...	...	0.002
Sodium chloride ...	...	...	...	...	0.165
Gelatin ...	...	...	...	...	0.327
Water ...	...	...	...	...	99.483
100.000					
III.					
Free iodine ...	...	...	...	...	0.012
Iodine as iodides ...	...	...	...	...	0.014
Sodium chloride ...	...	...	...	...	0.215
Gelatin ...	...	...	...	...	0.213
Water ...	...	...	...	...	99.546
100.000					

These figures agree closely with my own figures. I tested three samples, and the highest figures I found on analysis were 0.025 per cent. of free iodine with 0.015 per cent. of combined iodine. This concentration was too low to allow its rate of diffusion to be tested with any certainty.

TABLE II.—The Amount of Metal which Diffuses in Sixteen Days into a Tube of 6 mm. diameter filled with Water.

Solution.	Per cent.	Per cent.	Per cent.	
<i>Non-colloidal Solutions:</i>

Collosol ferrum ...	1.75 mg.	0.43 mg.	15*

\* This colour was, I believe, largely produced by the organic matter present.

#### PHARMACOLOGICAL ACTION OF COLLOIDAL PREPARATIONS.

A certain number of pharmacological tests were made to determine the action on living tissues of some of the preparations already mentioned.

##### Collosol Iodine.

The literature supplied by Messrs. Crookes suggests that the iodine in collosol iodine has an action on the body different from that of ordinary iodine. They state:

"The iodides have the disadvantage that being rapidly excreted they must be exhibited in large doses which often cause sickness, a foul taste in the mouth, and later, iodism with skin eruptions ... collosol iodine is free from these defects."

Collosol iodine is, of course, very unlikely to cause iodism, for according to the analysis given above a litre of collosol iodine only contains 6 grains of iodine (free and combined), and the dose recommended by mouth of collosol iodine is from 2 to 8 c.cm.

I determined the smallest amount of iodide and of iodine which, when taken by mouth on an empty stomach, would cause the appearance of a demonstrable amount of iodine in the urine, and then determined the effect of corresponding amounts of the colloidal preparations of iodine. The results are given in Table IV. It will be seen that collosol and oscol iodine apparently suffer exactly the same fate in the body as does ordinary iodine.

TABLE IV.

Drug Administered.	Quantity of Iodine Administered.	Amount of Iodine Appearing in the Urine in Four Hours.
Sodium iodide ...	Grams. 0.008 0.016	Presence just demonstrable. Presence clearly demonstrable.
Iodine ...	0.02	Presence just demonstrable.
Collosol iodine (50 c.cm.)...	0.012	Presence just demonstrable.
Oscol iodum (5 c.cm.) ...	0.003	None demonstrable.
" " (10 c.cm.) ...	0.016	Presence just demonstrable.

##### Colloidal Antimony and Colloidal Arsenic.

Cawston<sup>6</sup> and Wildish<sup>7</sup> claim to have cured leprosy with oscol stibium, and the total quantities of the preparation which they found effected a cure varied from 15 to 40 c.cm. These results are very remarkable, for 40 c.cm. of oscol stibium only contains 0.02 gram (1/3 grain) of antimony, and the quantity of antimony found necessary to produce cures in other diseases has been from 5 to 40 grains. Rogers,<sup>18</sup> who used colloidal antimony sulphide, recommended 2/3 grain antimony intravenously as a single dose.

Messrs. Crookes claim for collosol arsenicum that<sup>19</sup> "it is entirely non-irritant and does not cause any symptoms of arsenic intolerance; it has a very low toxicity while remaining therapeutically active."

Experiments were made, firstly to determine the minimal lethal dose of these colloidal metals, and secondly to determine the minimal dose required to exert a trypanocidal action. The minimal lethal dose and the minimal trypanocidal dose were determined by intravenous injection into mice. In case the protective colloids should have any toxic action on intravenous injection the minimal lethal doses on intramuscular injection in rats also were determined. These results are shown in Table V.

TABLE V.—The Minimal Lethal Doses of Antimony and Arsenic Preparations.

Drug.	Animal.	Mode of Injection.	Minimal Lethal Dose in Grams of Metal per kilo Body Weight.
<i>Antimony Preparations:</i>			
Tartar emetic ...	Rat	Intramuscular	0.012
Tartar emetic ...	Mouse	Intravenous	0.015
Oscol stibium ...	Rat	Intramuscular	0.02
Oscol stibium ...	Mouse	Intravenous	0.015
Collosol antimonium ...	Mouse	Intravenous	0.02
<i>Arsenic Preparations:</i>			
Arsenious acid ...	Rat	Intramuscular	0.006
Arsenious acid ...	Mouse	Intravenous	0.007
Collosol arsenicum ...	Rat	Intramuscular	0.017
Collosol arsenicum ...	Mouse	Intravenous	0.007
Oscol arsenicum ...	Mouse	Intravenous	0.01

The minimal lethal doses of non-colloidal arsenic and antimony agree with the results of other workers. Voegtlin and Smith<sup>8</sup> found, by intravenous injection into rats, that the minimal lethal dose of antimony given as tartar emetic was 0.018 gram per kilo, and that the minimal lethal dose of arsenic given as arsenious acid was 0.0053 gram per kilo. Fargher and Gray<sup>9</sup> found that the minimal lethal dose of arsenic injected as arsenious acid intravenously into mice was 0.0057 gram per kilo.

Külz<sup>4</sup> found, however, that the toxicity of a purified preparation of colloidal arsenic was far less than that of arsenious acid. The minimal lethal dose of arsenious acid injected intravenously as arsenious acid in a rabbit is 0.005 to 0.007 gram per kilo, but Külz found the minimal lethal dose of his preparation under these conditions was 0.03 to 0.035 gram per kilo. These results lead to the conclusion that colloidal arsenic is about one-sixth as toxic as arsenious acid.

Table V shows that the collosol and oscol arsenic and antimony were nearly as toxic as non-colloidal solutions on intravenous injection, but that the former were about one-half as toxic as the latter on intramuscular injection. The results with intramuscular injection may be due to the organic matter in the colloidal preparations hindering absorption. These results confirm the conclusion that a considerable proportion of the arsenic and antimony present in these preparations is in true solution, and suggest that the remainder is rapidly converted in the body into true solution.

The trypanocidal action of these substances was tested upon mice infected with *Trypanosoma equiperdum*. The trypanosomes were kindly supplied by Dr. C. M. Wenyon of the Wellcome Research Laboratory. The mice were infected with 0.1 c.cm. of the blood of a heavily infected mouse; this infection produced in most cases a trypanosomic count of from 100,000 to 300,000 trypanosomes per cubic millimetre of blood after three or four days. Untreated controls died in all cases within ten days, and usually within seven days of the infection.

The minimal dose of arsenic or antimony which cleared the blood of trypanosomes after four days was determined. The results are shown in Table VI.

TABLE VI.—The Trypanocidal Action of Antimony and Arsenic Preparations Injected Intravenously into Mice Infected with *T. equiperdum*.

Drug.	Minimal Curative Dose in Grams of Metal per Kilo Body Weight.	Minimal Lethal Dose in Grams of Metal per Kilo Body Weight.	Ratio M.C.D. to M.L.D.
<b>Antimony Preparations:</b>			
Tartar emetic ... ..	0.003	0.015	1 to 5
Oscol stibium ... ..	0.0076	0.015	1 to 2
Collosol antimonium ...	0.01	0.02	1 to 2
<b>Arsenic Preparations:</b>			
Arsenious acid ... ..	0.005	0.007	1 to 1.2
Collosol arsenicum ...	0.005	0.007	1 to 1.4

The results in Table VI show that in mice tartar emetic is superior to either collosol antimonium or oscol stibium as a trypanocidal agent, and that there is no pronounced difference between the activity of arsenious acid and collosol arsenicum.

The minimal curative doses obtained for tartar emetic and arsenious acid agree fairly well with those obtained by Voeghtlin and Smith.<sup>6</sup> These workers used rats infected with *T. equiperdum*, and obtained ratios  $\frac{\text{M.C.D.}}{\text{M.L.D.}}$  of 1/4 for tartar emetic and 1/1 for arsenious acid. These results show that these special preparations of arsenic and antimony have much the same trypanocidal action as non-colloidal arsenic and antimony.

#### Toxicity of other Collosol Preparations.

The minimal lethal dose to mice on intravenous injection of various other colloidal preparations was tested. The results are shown in Table VII.

TABLE VII.—Minimal Lethal Doses in grams of Metal or Alkaloid per Kilo Body Weight on Intravenous Injections into Mice.

Non-colloidal Preparations.		Collosol.	
Substance.	M.L.D.	Substance.	M.L.D.

Ferrous ammonium sulphate	0.05	C. ferrum ... ..	0.022
		C. argentum ... ..	0.015

The results in Table VII show that the collosol preparations tested have nearly the same toxicity as non-colloidal preparations of the same substances.

Heubner<sup>10</sup> found that with intravenous injection into rabbits the minimal lethal dose of the non-colloidal silver thiosulphate was 0.01 to 0.03 gram per kilo, while the minimal lethal dose of colloidal silver was 0.065 gram per kilo. That is to say that colloidal silver was less than one-half as toxic as an ordinary silver salt.

#### The Pharmacological Action of Colloidal Metals.

The facts as to the pharmacological action of colloidal metals have been obscured by various effects having been ascribed to them without adequate evidence, and also because many workers have used preparations which were to a large extent non-colloidal.

Metals in the colloidal form appear to exert only a feeble disinfectant action *in vitro*.

Marshall<sup>11</sup> prepared pure colloidal solutions of silver, and found that when tested over a period of ten minutes the colloidal silver had a disinfectant action only one-tenth as strong as silver nitrate. Marshall and Killoh<sup>12</sup> found that after *B. coli* had been covered with undiluted collosol argentum (1 in 2,000 silver) for ten minutes a vigorous growth resulted when the solution was removed; on the other hand, silver nitrate killed *B. coli* in five minutes at a dilution of 1 in 2,000,000. These results tend to show that colloidal metals will not exert a rapid disinfectant action.

Colloidal metals, if left in contact with bacteria for prolonged periods, will, however, act as efficient antiseptics. Simpson and Hewlett<sup>13</sup> found that on a twenty-four hour exposure collosol argentum acted as a disinfectant at a dilution of 1 in 200,000. This action of colloidal metals is, I think, probably due to their slowly breaking down and liberating free ions. Since metals in the colloidal form are non-irritant, this slowly exerted disinfectant action may be of considerable therapeutic value.

#### Fate of Colloidal Metals in the Body.

The suggestion is often made that metals in the colloidal form will continue to circulate for a long time in the blood; this is incorrect, as several workers have shown. Duhamel<sup>14</sup> found that when colloidal silver was injected into a rabbit 60 per cent. of the metal injected was fixed in the liver within fifteen minutes. Voight<sup>15</sup> in similar experiments, found that after three hours 81 per cent. of the silver was fixed in the liver, and that none remained in the blood. It appears from these experiments that colloidal metals will not circulate in the blood and act there as a disinfectant for more than a few minutes.

The results recorded in this paper concerning the action of collosol and oscol antimony and arsenic lead me to conclude that these are not superior as trypanocides to non-colloidal preparations; these results are inconclusive as regards the relative merits of colloidal and non-colloidal preparations because the proportion of colloidal metal in these preparations is uncertain. Külz<sup>4</sup> found that arsenic in purely colloidal solution was not superior to arsenious acid as a trypanocide in rats.

The chief therapeutic action of colloidal metals when given intravenously appears to be that they produce a general reaction similar to that produced by the injection of peptones or non-specific vaccines. Petersen<sup>16</sup> classes colloidal metals amongst the agents which produce "protein shock," and considers their use as a particular example of non-specific protein therapy. Since many of the collosols and oscols contain breakdown products of proteins in considerable amount as protective colloids, the injection of such preparations is particularly likely to produce the reaction known as protein shock. Unfortunately our present information as to the value of non-specific protein therapy is so vague that the knowledge that colloidal preparations may belong to this class of preparation gives little exact guidance to their therapeutic value.

#### Summary.

The physico-chemical tests employed indicated that the active principles of some of the "colloidal" preparations investigated were entirely in the colloidal form; in other cases the active principles were partly in colloidal form and partly in true solution; whilst in some cases the whole of the active principle appeared to be in true solution. Previous criticisms of the physico-chemical properties of some of these preparations have appeared in the *Journal of the American Medical Association*.<sup>17</sup>

The pharmacological tests employed failed to show any marked difference between the action of the "colloidal" preparations tested and the action of the same substances in true solution.

Note.—The expenses of this research were defrayed by a grant from the British Medical Association.

## FIVE CASES OF DIABETES MELLITUS IN YOUNG CHILDREN.

BY

F. JOHN POYNTON, M.D., F.R.C.P.LOND.,

PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL AND THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET.

The occurrence of five cases of diabetes mellitus in young children admitted within a short interval to one ward in a hospital leads me to think that at the present juncture in the history of this disease their publication may be of value. It is clear from the present literature that, for those who have few opportunities of studying a malady which is fortunately rare in childhood, it will be of importance to recognize the symptoms and, above all, the course of the disease at this early age, in order to obtain a correct perspective of the value of treatment by pancreatic extracts. It is in childhood that we see the pure type of virulent diabetes, and if very different results from those recorded in this series are obtained in the future there must be conviction that a great step forward has been made in medical knowledge. These cases were treated upon what until recently was considered to be the modern lines, and with the assistance of Dr. Spence and Dr. Donald Paterson, good medical clerks and devoted nurses, a whole-hearted attempt was made to study the effect of dietetic treatment and of such pancreatic extracts as were then available. The first case was an example of the type of problem that confronts us in hospital, and it will serve as an introduction to the main subject.

## CASE I.

A boy aged 7 years was admitted on September 5th, 1920, in a state of coma. He had suffered from diabetes for eleven months, and for four months had been under "a specialist," and was sent to us when comatose. If we turn to this boy's history we find it is a characteristic one. An only child of healthy parents, he had been for the first time attending school. For two weeks, though complaining of headache and thirst, he tried to do his work and then had to stop. For six months these two symptoms remained the prominent ones, but later others were added—hunger, irritability, constipation, and polyuria (5 to 6 pints per diem). His weight at first hardly altered. The final symptoms were increasing thirst; emaciation, some vomiting, abdominal pain, and fleeting pains in the limbs. Finally drowsiness and coma.

On admission he smelt strongly of acetone and was comatose. The action of his heart was feeble and his face grey. The abdomen was scaphoid, and the urine contained 2.2 per cent. of sugar. Death was sudden.

Among these symptoms I should dwell upon irritability as one which repeatedly appears in the young when the disease is making headway, and upon abdominal and other pains as occurring just before the onset of the coma.

There was no necropsy, and a more unsatisfactory case than this for all concerned can hardly be imagined. The second case was much more instructive.

## CASE II.

C. N., a boy aged 5½ years, was admitted on December 11th, 1919, with a history of symptoms of two months' duration. These symptoms were thirst, nocturnal enuresis, and occasional pain in the upper part of the abdomen. The sugar had been detected three weeks before admission, when the boy was attended by a doctor for colic due to eating green apples. Unless an attack of measles

in June, 1919, could be claimed as a factor in causation, there was not a single event in the boy's history to suggest a cause for the diabetes.

I dwell for a moment on the symptom of nocturnal enuresis. We see many cases of this disability, but very few are due to diabetes. It is, then, very unfortunate if one should overlook testing the urine thoroughly in a case of nocturnal enuresis and happen upon a diabetic child. This boy was well nourished and walked into hospital. His skin was dry and his tongue beefy. The knee-jerks were present but difficult to obtain; the fundi were normal. The urine had a specific gravity of 1042, was acid, contained 5 per cent. of glucose, and also acetone and diacetic acid.

## Treatment.

His appetite was poor. He was placed on a low diet of tea, boric, two eggs, and some minced meat. The calorie value of this diet was about 250, and in four days the urine was free from sugar, acetone, and diacetic acid.

We then started to test his carbohydrate tolerance, and by December 30th we had reached a diet of calorie value 914, which contained 78 grams of carbohydrate. The weight of the boy was 18 kilos, and accordingly the calorie value per kilo was  $\frac{914}{18}$  = practically 50 calories per kilo. Authority has stated that 40 are sufficient to maintain weight, but this boy barely held his own when in bed on 50 per kilo.

On January 1st we let him get up on the same diet for three days, and his weight increased, but a slight trace of sugar appeared in the urine. He returned to bed, whereupon the sugar disappeared, but his weight began to fall again.

By January 18th we had increased his carbohydrate tolerance to 85 grams, but after four days there was a slight trace (under 0.5 per cent.) of glucose. We accordingly decided that his carbohydrate tolerance was about 80 grams.

We then turned our attention more particularly to the fat tolerance, which we raised to the limit of 110 grams. During the next month we made tentative experiments in dieting, with these obvious points in view:

1. To obtain a diet which his parents could give him when he left hospital—one, that is to say, not too expensive for their resources, and fairly satisfactory for the boy.
2. A diet which, while keeping him sugar-free, maintained his weight.

This, whatever may be the opinion of others, is, I am convinced, very essential. We must try and maintain the weight in children. "Keep them thin" may be a motto for adults, but not for children. His diet finally had a calorie value of 835, but this would only admit two small slices of bread and two tablespoonfuls of milk pudding.

We failed—though the value of 46 calories per kilo body weight was attained—to maintain his weight in hospital, and after a long stay we sent him out with a fair diet. On admission he had weighed 2 st. 11 lb.; on February 15th, 1920, he weighed 2 st. 9 lb.

The diet for guiding his parents when he was at home was:

- Breakfast*.—One egg, one buttered rusk, and an ounce of bacon.  
*Lunch*.—Clear broth, one buttered rusk.  
*Dinner*.—Mince 2 oz., cabbage 6 oz., potatoes 2 oz.  
*Tea*.—One orange, one cup of milk, one buttered rusk.  
*Supper*.—One buttered rusk, one cup of cocoa.

This was the skeleton outline—fish and other vegetables could be substituted—and it was useful as a working basis.

Three weeks later he was readmitted, with urine specific gravity 1039, glucose 3.9 per cent., and a faint trace of acetone. We ascribed this to eating too many vegetables. He had gained weight.

Once again in hospital we had difficulty in getting him to maintain weight, but on a diet of 926 calories he just held his own. In a month, however, he was able to take 122 grams of carbohydrate and a diet of 1,124 calories, on which he had gained a pound. The urine (specific gravity 1014) was free from sugar and ketone bodies.

From March 31st to August, 1920, he lived at home and kept well but did not gain weight. Then he broke down with hunger, thirst, irritability, and polyuria. There was sugar but no acetone in the urine. He was admitted on August 28th, when only a trace of sugar was demonstrated. This time the specific gravity of the urine was never above 1026, and only traces of sugar and acetone appeared when we were building up his diet. The result on this occasion was encouraging, and he left the hospital in October, 1920.

About Christmas he became thirsty, lost strength, and suffered from polyuria. Alarm was aroused three days before he came to the hospital by a "bilious" attack and drowsiness.

On admission he looked ill and drawn, and his urine was loaded with ketone bodies and sugar. There was general abdominal tenderness. In spite of intravenous alkaline injections he died that night in severe convulsions.

The post-mortem examination naturally interested me greatly, for I had never had an opportunity of seeing one in a child after so protracted an attack of diabetes. His illness had extended over almost three years. As usual there was very little to see and no long description is needed. The liver was large, pale, and flabby; the kidneys appeared natural. The pancreas was small and soft, and microscopy showed no increase of fibrous tissue but atrophy of cells. The gland looked exhausted, and the cells of the islands of

Langerhans were atrophied and separated by connective tissue.

We know that much caution is required in interpreting post-mortem changes in the pancreas owing to the autolysis that occurs after death, but this was a clear case of atrophy of the pancreas.

The third case was of especial interest because there had been a history of only one week's illness.

## CASE III.

A girl aged 9 years was admitted on February 23rd, 1921, for sudden thirst, rapid wasting, and a nasty taste in her mouth. She had always had good health, and this was her first illness of any kind. Both her parents were healthy, her father aged 34, her mother 36.

The patient was thin and languid, passing 20 oz. of urine of a specific gravity 1042, containing 8.6 per cent. of sugar and ketone bodies. We put her on equal parts of milk and water, with a caloric value of 381. The sugar and ketone bodies disappeared, the urine falling in specific gravity to 1020; weight 3 st. 4 lb. Then we rebuilt the diet up to one of over 1,000 calories, and she gained steadily—leaving, sugar-free, in April. In June she was still sugar-free.

In September, 1921, she "caught a cold," and a fortnight later, being weak and generally ill, her urine was examined and found to contain sugar, and she was brought to hospital on September 24th. The child seemed quite ill and looked pale. Urine: specific gravity 1040, 2.9 per cent. sugar, ketone bodies present.

After admission she was very quiet and refused her food, and on September 28th fell into coma with profound collapse, dying early on the morning of September 29th. Efforts were made with an intravenous injection of a 2 per cent. solution of sodium bicarbonate—large doses by rectum—and drachm doses of glucose to restore her balance, but she never rallied.

Post-mortem examination was refused.

Here was a very remarkable and treacherous case. The first attack came like "a bolt from the blue," swift and threatening. The crisis passed and no case seemed to be doing better, for there was steady gain in health and weight and disappearance of the sugar. For months the child seemed well—and then came an infection in the shape of a "cold," and once more the swift onslaught. It was possible that the few days in hospital before death were not managed to the best advantage, but I do not think that this made any essential difference to the final issue. We must be wise indeed if, with scant opportunities for seeing diabetes in childhood, we can always anticipate an attack of coma.

Watching a series of these cases would convince one that there is something more than diet involved in these sudden relapses. Not for one moment do I suppose that, good though these children were and devoted their parents, it is probable that a strict diet can be maintained. One of the children was a member of a working man's large family—can one believe that the children did not have pity upon the sister whose diet was so dull, and provide her with occasional treats? Granting this, children who left hospital losing ground in every way actually improved in some instances at home. The breakdowns were more mysterious than a matter of diet—for example, when the weather became cold and treacherous and there were sore throats and coughs, my various cases would come back within a week or ten days with sugar in the urine. Three came back into the ward within a week, although from different families and different localities.

## CASE IV.

My next case, a boy aged 8 years, had been suffering from lassitude, weakness, thirst, and polyuria for eleven months. His condition first attracted attention by his general weakness after he returned from school.

He was admitted to hospital in September, 1919, in what as the sequel showed was to be a feature of his case—an acute condition of acetonaemia. I did not see him then, and can only record that he went out improved. He appeared to have kept well, and certainly gained weight for nine months, when, fourteen days before he came under my supervision, he became irritable, weak, sleepless, and suffered from polyuria.

His second admission to the hospital was August 9th, 1920. The only history we could get was an injury to his right calf before the first symptoms of the disease commenced. The parents were healthy, as also was his only sister.

This boy was a very home-sick one, and on his readmission he had an acetonaemic attack, with vomiting. The specific gravity of the urine was 1010; it contained no sugar, but great excess of ketone bodies.

In this case it was urgent to control particularly the fats, and as the ketone bodies diminished a little sugar appeared and the child lost weight. The strict diet soon got rid of sugar and ketone bodies, but the loss of weight called for an advance upon this.

The blood was examined on August 24th by Dr. Spence, who found the blood sugar normal, but the curve a true diabetic one; as the chart exemplifies.

By August 27th he was so much better that we had him on a practically normal diet, except that bread and potatoes were cut

down by half because of an occasional slight leakage of sugar. From the 19th to the 26th he was in fact on a good diet, free from all sugar and ketone bodies; but his blood sugar estimation, though giving a normal blood sugar content, showed after carbohydrate a true diabetic curve.

We eventually sent him out on October 12th sugar-free, though, in spite of every care, sugar would sometimes appear mysteriously in small quantities. I thought, in spite of the blood test, that we were going to have a successful result if we could only keep reasonable control of him when out of hospital. His diet was the following:

Breakfast.—Milk one glass, one egg, one rusk and butter.

Lunch.—One glass of milk.

Dinner.—Clear broth, mince, cabbage, potato.

Tea.—One orange, one glass of milk, one egg, one rusk and butter.

Supper.—One rusk and butter, one cup of cocoa, cheese, lettuce.

The boy kept well from October until the beginning of February, 1921, attending the hospital every fortnight.

In February, within a week he became irritable, drowsy, languid, and thirsty. He was admitted to hospital threatening coma, with sugar 4.8 per cent. and ketones in the urine, which had a specific gravity of 1040.

An in- was some bronzing of the face and a yellow palms of the hands. He was treated with skimmed milk, given glucose, 2 drachms four-hourly, and large doses of sodium bicarbonate by the mouth.

He rallied well, and we raised him eventually to a diet of 1,616 calories, on which he just held his own. After two months in hospital he left with a sugarless and ketone-free urine in April. This time we had difficulty in ridding the urine of the ketone bodies, which made me uneasy as to the future.

Until August, 1921, he kept on the whole well, though leaking sugar at intervals, but at the beginning of this month he developed headache, polyuria, thirst, pains in the limbs, drowsiness, and deep breathing. The urine had a specific gravity of 1026, and was loaded with sugar and ketone bodies. The knee-jerks were absent. Treatment with stimulants, intravenous sodium bicarbonate, calomel, and sodium bicarbonate by the mouth saved him, but for several days his life hung in the balance. This time with all our efforts, and with occasional starvation days, we could never get him free from some sugar or acetone. He left the hospital in October, 1921.

He left the hospital losing ground and in an apparently hopeless condition, but it would have been sheer cruelty to keep him longer away from his home, particularly as we were doing him no good. To my astonishment he then commenced to improve, and though not free from sugar kept well through the winter, until February, 1922—that is, for four months. Then all his symptoms reappeared synchronously with the formation of a small abscess on his scalp. He came to hospital on February 14th, smelling strongly of acetone, breathing deeply, and very drowsy. The urine had a specific gravity of 1032, and contained sugar and great excess of ketone bodies. In spite of every effort he died in coma on the 6th.

The post-mortem examination showed, as in Case II, a fatty liver, but the pancreas was shrunken and even more wasted than in the former case. Microscopy showed no active reaction, no trace of inflammatory change, but similar shrinking of the cells of the islets and relative increase of connective tissue.

## CASE V.

The last case, a girl aged 7½ years, was admitted on May 28th, 1920. This case we got early, for there had only been three weeks' history. The symptoms were: inordinate eating and drinking, rapid wasting, and polyuria, the urine being noticeably pale in colour. There was not the slightest hint in the family or personal history, or in the surroundings, as to the cause of this sudden breakdown.

The child looked ill and was wasted, and suggested the diagnosis of diabetes. The specific gravity of the urine was 1045, and there was much sugar with ketone bodies.

By June 12th, on skimmed milk, with caloric value reduced to 513, and carbohydrate 52 grams, the sugar in the urine was reduced to a trace and the ketone bodies eliminated.

In July she was keeping free from sugar.

This child left hospital in October, 1920, free of sugar and ketones, apparently well, but with a blood curve of the diabetic type as shown by Dr. Spence. She kept well, but unfortunately ceased to come up to hospital for two months.

Previous to her next admission in February, 1921. It would be wearisome to detail the subsequent history, but, in a few words, the child broke down again in February, 1921, and once more we sent her out, in April, 1921, sugar-free and looking well, but in the notes I had expressed the opinion that there was increasing difficulty in attaining this result and that the outlook was bad. In July it was interesting to read the note of an enthusiast below this to the effect that she was looking splendid and was sugar-free.

Shortly after this note, in the same month, she broke down again. In her case we had difficulty in raising the calorie value as there was some sugar appearing; and particular difficulty was experienced in trying to raise the carbohydrate tolerance. However, in September we had got the calorie value up to 1,546, carbohydrates 50 grams, and the patient had gained a little weight. On September 30th half a slice of bread brought back sugar, and later some mince produced the same result.

In October we managed to give one ounce of potato and a quarter of an ounce of bread, and a diet of calorie value 1,600. Now and again a trace of sugar would appear, but we then discharged her under supervision with the following diet:

*Milk*.—8 oz. every four hours.

*Breakfast*.—One egg, cheese 1 oz., two tomatoes, weak coffee, bread 1/4 oz.

*Dinner*.—Broth, cabbage, 8 oz., potatoes 1 oz., fish 2 oz., cheese 1 oz., one egg.

*Tea*.—Broth, one orange, lettuce 6 oz., cheese 1 oz., one egg.

*Supper*.—One egg, weak tea, an onion, bread 1/2 oz.

In 1921 a yellow discoloration was noticed on the palms of the hands and soles of the feet.

Once more she kept well through the winter—her mother taking infinite trouble—but broke down again in February, 1922. From that date onward she always appeared thin and drawn, but was out of hospital until the autumn, when again all the symptoms returned: diet proved ineffectual, and the child became very unhappy. It was apparent that the last stage was reached, and at urgent request she went home, dying in coma in November, 1922. There was no necropsy.

The experience gained from these cases was not unexpected, but was very disappointing, for we had all, according to our lights, worked most diligently at them; yet all five died within three years. In all the cases of any duration we invariably went through three stages of thought: first the belief that we were succeeding—a belief which was never confident; then the uneasy feeling that we were losing ground; and finally, the realization that our efforts were fruitless. We protracted the illnesses, but nothing more, and this very partial success was so unsatisfactory from the children's point of view that had not there been always a hope that some new advance might appear, or some unexpected improvement arise, it seemed hardly worth while.

The course of the illnesses and condition of the pancreas suggested to me an abiotrophy comparable to a myopathy.

That diet only touched the fringe of the problem seemed also beyond dispute. No doubt our methods were open to criticism—no dietetic therapy could escape this fate—but no criticism would alter, in my opinion, the essential fact that the disease was materially untouched.

The remarkable periods of comparative quiescence, the unexpected outbursts, and the sudden improvements under apparently less favourable surroundings, all pointed to a mysterious hidden hand working against us.

Finally, with new methods in sight, I would venture to repeat that this series of cases may be of some value to those with fewer opportunities to form a clear idea of new results. If, as we all hope, these are much more favourable in the diabetes of the young, they will be seen more clearly against this black background—painted, as it were, at the eleventh hour.

This fact, if nothing more, is to be learned from these cases—that even in the young, with careful dieting (and presumably some care will always have to be taken with the diet), sugar and ketone bodies may disappear for weeks and months. When I write "disappear" I mean this in a practical sense—namely, ordinary careful examinations at reasonable intervals compatible with workaday medical practice.

Any remedy may, then, produce this effect, or rather be coincident with it; but if this remedy in addition wards off acetonaemic attacks, or tides children over the sudden relapses, we shall be in a better position.

## REMARKS ON BOTULISM AS SEEN IN SCOTLAND IN 1922.

BY

T. K. MONRO, M.D., F.R.F.P.S.,

REGIUS PROFESSOR OF MEDICINE IN THE UNIVERSITY OF GLASGOW;

AND

WILLIAM W. N. KNOX, L.R.C.P.S. EDIN., L.R.F.P.S.,

GAIRLOCH, ROSS-SHIRE.

THE general circumstances attending the food poisoning tragedy at Loch Maree Hotel in August, 1922, became sufficiently familiar to the public through the agency of the press and the proceedings at the public inquiry; but as this outbreak was the first of its kind known to have occurred in Britain it has been thought advisable to describe its principal features, so far as they came under the notice of the medical observers. It will be borne in mind that the scene of the calamity was a remote spot some twenty miles distant from the nearest railway station, and ten miles from the residence of the nearest medical practitioner. Some of the victims and other guests had frequented the hotel in the fishing season for many years, and it was admitted by those who were in a position to know that the management and catering at the establishment were of a particularly high order.

All was well at bedtime on Monday, August 14th. On the morning of Tuesday, August 15th, six guests were suffering from nervous symptoms. On Tuesday afternoon one, and on Wednesday morning another, of the ghillies became indisposed, and thus the number of sufferers was increased to eight.

Before giving notes of the individual cases we may summarize the more general features of the illness as follows: The onset was with diplopia and unsteadiness on standing (less or none of the unsteadiness while lying in bed); palsy of ocular muscles (internal or external, or both); palsy of elevators of upper eyelids with contraction of frontals; inability to protrude the tongue; nasal or thick speech, or loss of speech; dysphagia; palsy of diaphragm; paresis of costal respiratory muscles; paresis of upper limbs and dorsal muscles of neck; complaint was made with regard to the throat (the patient pointing to the region of the larynx or of the pharynx); vomiting was severe in some cases, slight or absent in others; diarrhoea in some; in some cases complaint was made of abdominal discomfort or pain. There was no fever, no cough, and no disturbance of sphincters. The heart was normal; intelligence was preserved; there was little or no headache.

In most of the cases the illness began on the Tuesday morning with diplopia and unsteadiness on standing. The nervous symptoms were more obtrusive than the digestive; and, so far as was made out, the damage was confined to motor neurones, and mainly, if not solely, to lower motor neurones. The cranial nerves involved were apparently the third, fourth, sixth, ninth, tenth, eleventh, and twelfth. In certain cases there was involvement also of motor elements in the spinal cord, and particularly in the cervical region. It was surprising to note how completely the facial muscles appeared to escape, while their neighbours supplied from the brain stem above and below the facial nuclei suffered so severely. The condition of the face below the level of the eyes was therefore in striking contrast to that which is often seen in the victims of the Parkinsonian type of lethargic encephalitis.

One patient called attention to his lips, but it was not clear whether he referred to a motor or a sensory disturbance. No other sensory defect was recognized in his case, and, so far as could be ascertained by objective examination, the power of the orbicularis oris, if impaired at all, was not lost.

All the patients succumbed. The most fortunate were those who died on the first day, since they were cut off by rapid failure of the heart, with very little suffering. Those who survived for a day or two had the greatest physical suffering, and it was painful to witness how for hours, and while in full possession of consciousness, they had to maintain the struggle for breath which resulted from the paresis of the ordinary muscles of respiration; and to this cause of distress there was added the inability to see, to speak, or to swallow. Those who survived longest formed an intermediate group with respect to the amount of physical suffering.

THE second international congress of military medicine and pharmacy will be held in Rome from May 28th to June 2nd, with General della Valle, Director-General of the Italian Army Medical Service, as president. The subjects for discussion include the relation of the transport service to the medical service; the collaboration between the civil and military authorities in matters of health, physical education, tuberculosis, venereal disease, alcoholism, etc.; disinfection and disinfection in peace and in war; the treatment of chest wounds; and the scope and methods of chemical laboratories in relation to the army. Further information may be obtained from the Secretary of the Congress, at the Ministry of War (Direzione Centrale del Servizio Sanitario Militare), Rome.

## Notes of Cases.

## CASE I.

Male guest, aged 70. On rising from bed at 3 a.m. on Tuesday, August 15th, began to suffer from giddiness and double vision. He had also severe vomiting and diarrhoea. By the middle of the day he had difficulty in . . . in the evening speech was severely affected, and . . . was one of collapse. He died at 8 p.m. apparently from cardiac failure, and without having suffered much from respiratory distress.

## CASE II.

Female guest, aged 56. Began to have diplopia on Tuesday morning. About the middle of the day she vomited, and when she was seen shortly afterwards her tongue was dirty and her speech was difficult to follow. She was able to sit up in bed and did not look very ill. Later on she became unable to swallow. When seen about 10 p.m., she was lying quietly on her side, intelligent, and free from evident distress, but cyanosed in the face. Her pulse rate, which not long before had been 72, was now found to be over 130. She died about 11 p.m.

## CASE III.

Male guest, aged 22. Could not see properly on Tuesday morning. He had diplopia while in bed, and on trying to rise felt giddy. When he complained of double vision squint was noticed by his friends, and he complained of discomfort in the mouth. Vomiting began in the afternoon. He could speak intelligently till 5 p.m. or later. Late on Tuesday night it was noted that the pupils were dilated. The fundi were easily seen and were normal. The patient was speechless, and communicated by writing, complaining of choking by spittle. The urine was abundant and of nearly normal colour.

At 3 a.m. on Wednesday some jerking of the arms was observed. When seen about 9.30 he was quite intelligent, and the pulse and breathing were normal, but he was unable to open the eyes properly, or to speak, or to swallow, or to keep up his head while sitting in bed. The knee-jerks and abdominal reflexes were absent. The diaphragm appeared not to be acting. Death took place at 12.30 p.m. that day (Wednesday, 16th).

## CASE IV.

Male guest, aged 66. Began to suffer on Tuesday morning from double vision and giddiness. When he was seen at a late hour that evening his voice was very thick. The pulse rate was 80.

On Wednesday there was no movement of the eyeballs. The patient raised the eyelids with his fingers to see who was beside him. The right pupil was slightly contracted. The tongue could not be protruded. The knee-jerks and abdominal reflexes were absent. The pulse rate was 92. The voice was at length lost completely, so that the patient made signs in trying to communicate with others. Dyspnoea became severe and caused intense suffering, the patient being unable to lie down or to remain still even in a sitting position. Consciousness remained almost to the end, and hypodermic injections of morphine were the only means found to give temporary relief to the suffering. Death occurred at 9.30 p.m. on Wednesday, August 16th.

## CASE V.

Female guest, aged 45. On getting out of bed on Tuesday about 6 a.m. felt dizzy and saw double. She had eaten potted-meat sandwiches about 1 p.m. on Monday, and was quite well when she went to sleep at 11 o'clock the same evening. When she was seen late on Tuesday night she had diplopia on looking to the left, dysphagia, slight defect of speech, and sluggishness of the pupils. She remarked spontaneously that she had been drowsy all day. During the ensuing night there was diarrhoea.

On Wednesday morning there was cyanosis. No movement of the diaphragm was detected. The hands were weak. The knee-jerks were normal, the plantar reflexes flexor, and the abdominal reflexes absent. Speech had become worse. There was vomiting of slightly fetid yellow material. The pulse rate was 92. The heart was normal.

For a brief period there was stridor suggesting abductor paralysis. Aphonia ultimately became complete. There was frequent complaint of the throat, and the patient often inserted her fingers into her mouth, with the purpose, as it seemed, of inducing vomiting, but without success. Inspection of the fauces showed no abnormality. Temporary improvements were observed in this case once or twice. In the later stages of the illness the muscles at the back of the neck were paralysed, so that the head hung forwards, and the upper limbs appeared to be seriously weakened. In the last few hours there was orthopnoea with restlessness and great distress referred to the throat. Consciousness was retained practically to the end, which took place at 4.5 a.m. on Thursday, August 17th.

## CASE VI.

Ghillie, aged 35, was out with Case V and her husband on Monday, and with the husband alone on Tuesday. Before he left the boat on Tuesday afternoon he had begun to feel unwell. When he was seen late on Tuesday night he complained of his throat, and of pain and tenderness in the upper abdomen. The bowels had moved several times that afternoon. There was no diplopia. The temperature was non-febrile.

On Wednesday the speech was very thick. The tongue was dry, and was not fully protruded. There was pain at the throat, with inability to swallow either food or drink. There was no vomiting. The patient was quite intelligent, and communicated with others in writing. The left pupil was slightly larger than the right; both contracted to light. Lateral deviation of the eyeballs was defective. There was no nystagmus nor diplopia.

On Thursday he was seen about 6.30 a.m. He was unable to speak or to swallow. He was intensely restless and unable to remain either in the recumbent or in the sitting posture. He was eager to be removed by motor to his own home, some thirty miles distant, and his wish was respected. He died at 1.30 p.m., an hour after arrival.

## CASE VII.

Male guest, aged 60, husband of Case II. Found on Tuesday morning that he was seeing double and that he staggered when on his feet. He told his wife about the double vision, and she said that she had the same symptom. The patient went rowing and fishing on the loch that day, hoping that the exercise would do him good, and he dressed for dinner in the evening.

Next day (Wednesday) he rose again, but in the afternoon he thought his speech was slightly affected, and he had decided ptosis. On Thursday he remained in bed, but was not obviously worse. For a day or two there were temporary improvements.

On Friday evening the voice was thicker; protrusion of the tongue was defective; movement of the palate was impaired but not lost; and there was ptosis on both sides. The external recti were weak, especially the left, and squint was perceptible, particularly when the patient looked to the left. Diplopia, however, was not now admitted. The pupils were of medium size and contracted actively to light. The movements of the facial muscles and the power of grasping were well preserved. The knee-jerks were normal or slightly increased. The plantar reflexes were flexor; the abdominal reflexes were absent. There was no disturbance of the bladder. The pulse was 84.

During the ensuing night the patient had a good deal of sleep, but on Saturday morning ptosis was complete and the voice was so thick that his speech was very difficult to understand. He tried to communicate with those around by writing, but in order to see the pencil and paper he had to raise the eyelids with his fingers, and then he found that he could not manage without his glasses, and an attempt to hold the eyelids up and to keep the glasses adjusted at the same time proved a failure. For a time it remained possible to detect a few words which he tried to whisper. In the afternoon he was seen by Dr. Brown Kelly, who found that sensation was preserved in the palate and posterior pharyngeal wall. There was reflex movement of the soft palate on probing with a wire, but there was no movement on phonation. The power of protruding the tongue was diminished but not lost. The patient called attention to the lips, but the muscles were not obviously paralysed, and it was not quite clear what the symptom was. He seemed also to indicate that his right upper limb was weakened.

On Sunday he was unable to swallow. During the ensuing night he was restless, but he did not have the intense respiratory distress noted in some of the other cases. He died on Monday, August 21st, about 1 p.m. The brain was removed by Mr. Colt, who sent one portion to Dr. Cruickshank of Aberdeen, and the other to the Scottish Board of Health.

## CASE VIII.

Ghillie, aged 40 (boatman to Case I). Complained on Wednesday morning, August 16th, of abdominal discomfort on rising. There was sickness also in the morning, but not vomiting. In the course of the day he had a feeling of heaviness in the eyes, and saw double when he looked far ahead. Movement of the eyeballs was good, and did not induce diplopia. The pupils were of medium size and contracted to light.

When seen on Thursday he was in bed, but was not obviously worse. He spoke of some difficulty in swallowing, but there was no pain. The movements of the eyes seemed satisfactory. In the course of that evening or night he began to complain of his throat.

On Friday night he was complaining of pain near the lower angle of the left scapula. The heart, lungs, spleen, and superficial lymph glands all seemed to be normal. The area of hepatic dullness was somewhat reduced. The pulse was regular, 72 a minute. The tongue had a white fur. There was no vomiting. The bowels were constipated, but had been moved by enema. The tongue was protruded pretty well. There was very little movement of the palate, and the power of swallowing appeared to be reduced. The fauces were normal. The voice was thick. There was no deafness nor tinnitus. The power of grasping was good. No noteworthy change was discovered in the reflexes. During the night he had a good deal of sleep. On Saturday morning he was unable to swallow, but was free from distress. The pulse rate was 70. The respirations were 19 a minute and were free from embarrassment. The tongue was dry. He was seen that afternoon by Dr. Brown Kelly, who found that the tongue could be protruded and moved sluggishly from side to side. The palate was motionless and showed no reflex contraction on probing. The power of less and showed no reflex contraction on probing. The power of swallowing was lost, and there was a gurgling sound in the throat owing to the accumulation of mucus, which could neither be swallowed nor expelled by coughing.

On Monday, August 21st, at 11 p.m., the patient died peacefully of cardiac failure.

Reckoning from 1 p.m. on Monday, the shortest incubation period was fourteen hours (Case I), and the longest about forty-three hours (Case VIII). The patient (Case VIII) who was the last to become ill and the last to die was boatman to the one who was the first to become ill and the first to die (Case I). As the ghillies may have eaten the poisonous food some time later than the anglers, the longest incubation period may really have been less than the forty-three hours.

Cases I and II died on Tuesday, August 15th; Cases III and IV on Wednesday, August 16th; Cases V and VI on Thursday, August 17th; and Cases VII and VIII on Monday, August 21st. The longest periods of survival from the onset of symptoms were six and a quarter days (Case VII) and five and a half days (Case VIII); the shortest were from fifteen to seventeen hours (Cases I and II).

Of the various means used to help the sufferers, the only one which gave any obvious benefit was morphine, and the relief was only of a temporary character.

With regard to the nature of this outbreak of illness, it was soon possible to set aside early suspicions as to the presence of poisonous berries in the black-currant tart consumed at dinner, and as to lethargic encephalitis. A careful inquiry as to the various articles of food consumed at dinner in the hotel, and at lunch on the loch, on the preceding day, showed that with one doubtful exception (subsequently found not to be an exception), the sufferers had all partaken of certain sandwiches made with potted wild duck. In the course of Wednesday, August 16th, we met in consultation with Dr. Maclean, M.O.H., and Dr. Brodie, school medical officer from Dingwall, Dr. Carnegie Dickson from London, and Dr. Cox from Preston; and all were agreed that the illness was due to food poisoning and that the potted meat was probably the offending substance. In course of time it became quite evident that botulism was the particular form of food poisoning with which we had to deal.

At the public inquiry held by Sheriff McIntosh at Dingwall on September 5th to 7th it was shown that some individuals who had partaken of the wild-duck sandwiches had not suffered any harm. This was accounted for by the fact that two pots of wild duck had been used for the sandwiches on the Monday morning. It also appeared that no other pot prepared by the manufacturers had ever been known to be harmful. The inquiry showed that the infection must have been in the pot when it left the factory, but it failed to show how or where the infection had taken place.

While the symptomatology was of itself sufficient for a diagnosis, there was a general feeling of satisfaction when it was learned that the results of laboratory investigations had removed any possibility of doubt. Dr. Cruickshank of Aberdeen gave evidence that the histological examination of a portion of the brain from Case VII was in accordance with the diagnosis of botulism, and Mr. Bruce White, B.Sc., of Bristol, working for the Scottish Board of Health, stated that he found *Bacillus botulinus* and its toxin in the remains of one of the pots of wild-duck paste.

Among the colleagues whose valuable co-operation we had in examining the patients, in trying to relieve their suffering, or in endeavouring to elucidate its origin, were Drs. Maclean and Brodie (Dingwall), Carnegie Dickson (London), Cox (Preston), Brown Kelly (Glasgow), Colt and Craickshank (Aberdeen), and Dittmar and Leighton (Edinburgh); and, in addition, Mr. Bruce White (Bristol).

## OBSERVATIONS ON THE CAUSE AND CURE OF CHRONIC RHEUMATISM.

BY

E. HARDING-FREELAND, F.R.C.S.Eng.,

BERNE, SWITZERLAND.

THE general characteristics of rheumatism, popularly so called, must be apparent to even the most casual observer. Everyone, I take it, will agree that rheumatism is a disease which is very prevalent, usually very painful, often very disabling, and always very liable to recur in spite of treatment. With such a picture presented to our view it seems strange that rheumatism of the chronic type has from time immemorial been treated with scant courtesy alike by writers of books and practising physicians. The references to this type of rheumatism in the textbooks are usually meagre in the extreme—as a rule the subject is mentioned merely to be dismissed in a few cursory words, while in practice any ache or pain which cannot be conveniently referred to any cause in particular is labelled "rheumatic."

So it happens that under the term "rheumatism" there have been grouped together a large number of conditions which bear a certain superficial resemblance to each other, as far as their external manifestations are concerned, but differ widely the one from the other when their fundamental nature comes to be investigated. They are due to widely dissimilar

causes, and must therefore be considered to be different and distinct conditions. The result is that the term "rheumatism" has come to be very loosely used, and has come to denote a medley of symptoms rather than any definite disease.

### The Nature of Rheumatism.

At the outset we are confronted with the all-important question—What is rheumatism? To this question it is essential that he who sets out to cure the ailment should be prepared to give as definite an answer as possible if he expects his efforts to be rewarded with success. Observation and experience extending over many years have led me to the following conclusions, among others, as to the nature of this disease.

1. That rheumatism is a definite disease.
2. That rheumatism is an infective disease due to the invasion of the part affected by a specific microbe—the *Streptococcus rheumaticus* of Poynton and Paine.
3. That the acute, subacute, and chronic types of rheumatism are variant forms of the same disease, the underlying pathological conditions and essential cause being the same.

To put the matter more concisely, rheumatism is a specific infective disease due to the *Streptococcus rheumaticus*. The validity or otherwise of this proposition I do not propose to discuss here, my present purpose being to show the practical results which may be achieved by adopting this proposition as a working hypothesis and a basis of treatment.

### Basis of Treatment.

Every practising physician must be painfully conscious of the futility of trying to cure rheumatism by what may be termed the ordinary methods of treatment. These remedies, it is true, seldom fail to give temporary relief; but equally seldom they fail to prevent a relapse. To my mind, this inveterate tendency to recur in spite of treatment, which must be patent to even the most casual observer, must be considered the outstanding feature of rheumatism. That being so, it follows that any method of treatment which is capable of effecting a permanent amelioration or cure must be not only capable of breaking up the attack in being but also capable of preventing the occurrence of any prospective attack.

In other words, assuming rheumatism to be an infective disease due to a specific microbe, to effect a cure it is essential to compass the destruction of the microbes already lurking in the tissues, and to render the tissues immune to attack by other microbes which may subsequently gain access to the circulation. In the present state of our knowledge the only method of treatment which can be expected to fulfil these conditions is vaccine therapy.

### Necessary Preliminaries.

Before, however, undertaking the treatment of a case of alleged rheumatism by vaccines or any other method of treatment it is necessary, as a preliminary, to make sure—or to make as sure as possible—that it is a case of genuine rheumatism with which we have to deal, and not one of its many counterfeit presentments. In other words, we must take pains to determine that the case in question is a true *Streptococcus rheumaticus* infection, and not some other form of infection which gives rise to similar manifestations. To this end all the various conditions which are known to give rise to symptoms closely resembling those of rheumatism should be closely considered and excluded. A careful study of the case in general, its history, course, symptoms, and physical manifestations, and, wherever necessary, the application of appropriate tests, will in the vast majority of cases lead us to a correct conclusion as to its true nature.

### Vaccine Therapy.

Having determined the identity of the disease, and that it is a case suitable for vaccine treatment, the subsequent course is comparatively easy going. Practically the only difficulty which presents itself is the question of dosage. This must necessarily vary with the individual, and can only be determined by experience. If the initial dose produces an undue reaction, the subsequent dose should be reduced; if, on the other hand, no reaction is apparent, the subsequent dose should be increased; and so on until a dose is found which produces a minimum of reaction. In other words, the ideal dose is the maximum of vaccine which produces the

minimum of reaction. Once this is found the rest is easy. It is only necessary to repeat the dose week by week until such time as the symptoms have disappeared, or until no further improvement is obtained.

Circumstances of course may occur when it may be considered advisable to increase or decrease the dose or the intervals between the doses, temporarily or permanently. Every case must be treated on its merits.

#### Supplementary Treatment.

Let it not be thought for one moment that I am advocating vaccine therapy as the be-all and end-all of treatment. On the contrary, with rheumatism, as with all other diseases, no remedial measures should be neglected which help to bring about the best possible results. Experience, however, has led me to regard vaccine treatment as essential, and other remedial measures as subsidiary, but by no means unimportant, seeing that, in the vast majority of cases, they are usually desirable, and often necessary.

Symptoms of various kinds must be treated from time to time as they arise. The general health of the patient must be attended to, and every effort must be made to get him as fit as possible. The state of the digestive organs should be investigated and any tendency to indigestion rectified. The question of diet should not be overlooked, and, although it is seldom necessary to recommend an unduly restricted diet, it is often necessary to formulate a dietary suited to the digestive capacity of the individual. Speaking generally, a somewhat generous but plain and wholesome diet is indicated. Vaccine treatment seems to improve rather than diminish the digestive capacity. For obvious reasons it is essential to ascertain that the bowels, skin, and kidneys are functioning well, and, if not, to regulate their activity by appropriate measures.

Massage, active and passive movements, radiant heat, Turkish baths, resolvent applications, etc., should not be neglected, especially in the more chronic cases, which are often accompanied by much swelling and stiffness.

Such, then, is a brief outline of the method of treatment which I have been accustomed to adopt for some years past in cases of chronic rheumatism.

#### Analysis of Cases.

The results, which I have recently reviewed and been at pains to verify, are set forth in the following analysis. Only those cases are included in which sufficient time has elapsed to render them of any value in computing results, and in which the results are definitely known. An examination of the cases shows that, with few exceptions—which have not been included—they all fall naturally into five anatomical groups, as shown in the following tabular statement, which also shows the nature and number of the cases treated in each group, and the results obtained.

	Cases.
Articular rheumatism (arthritis) ... ..	52
Cured or markedly relieved ... ..	42
Slightly relieved or failed ... ..	10
Muscular rheumatism (lumbago 10, other forms 14) ... ..	24
Cured or markedly relieved ... ..	20
Slightly relieved or failed ... ..	4
Neural rheumatism (sciatica 6, other forms 14) ... ..	20
Cured or markedly relieved ... ..	15
Slightly relieved or failed ... ..	5
Pharyngeal rheumatism (tonsillitis) ... ..	12
Cured or markedly relieved ... ..	12
Cerebral rheumatism (chorea) ... ..	4
Cured ... ..	4
Total number treated ... ..	112
Cured or markedly relieved ... ..	93=83%
Slightly relieved or failed ... ..	19=17%

Some explanation is necessary with regard to the terms used in describing results. "Cured" means that the symptoms have completely vanished, and that there has been no recurrence for upwards of a year. "Markedly relieved" includes cases of more recent date, which have remained well for from six to twelve months. "Slightly relieved" means that there was no very marked improvement in the condition, or what improvement had occurred was not permanent. "Failed" speaks for itself.

It should be noted that most of these cases were of long standing, and all had lapsed, or were tending to lapse, into the chronic phase, with frequent recurrences; and that the majority had been treated with the ordinary methods of treatment with little or no benefit. The following cases in epitome exemplify the type of case treated.

#### Articular Rheumatism.

*Case 1.*—Male, aged 35. Origin, attack of rheumatic fever. Duration, nine months. The condition when first seen included pain, swelling and stiffness of the hips, knees, and ankles; locomotion was only possible with the aid of two sticks; the general health was fair. After three injections the swelling disappeared; pain and stiffness were less; he was able to move about more freely, but still used a stick. After five injections, voluntary movements of the joints were free; he was able to get about fairly well, but his legs were still weak; he could not altogether dispense with a stick, but pain was practically gone; there was still some stiffness after resting. After eight injections all symptoms had gone; he could walk well and returned to work. He was under treatment for seven weeks.

*Case 2.*—Female, aged 66. Origin, subacute attack. Duration, six years. When first seen all the joints were involved; she was unable to do anything for herself, and was bedridden, with marked deterioration of health. After twelve injections she was able to get about and could use her arms and hands freely. Her general health was much improved, but she was still weak. After sixteen injections all symptoms had disappeared; she could walk well without assistance and use her hands and arms for all practical purposes. Her general condition was good. She was under treatment for four months.

#### Lumbago.

*Case 3.*—Male, aged 47. Origin, subacute attack. Duration, three years. His condition included pain in the back, limitation of movements, and stiffness; the pain increased on movement, rendering locomotion difficult. After eight injections all symptoms had disappeared. He was under treatment for six weeks.

#### General Myalgia.

*Case 4.*—Male, aged 30. Origin, "chill." Duration, two years. When first seen he had general muscular pains, varying with changes in the weather, worse at night. After five injections the pain had gone. He was under treatment for four weeks. Note: This case is typical of the majority of cases of generalized myalgia treated.

#### Sciatica.

*Case 5.*—Female, aged 28. Origin, acute attack, attributed to sitting on a damp seat. Duration, three weeks. When first seen the attack was lapsing into a chronic phase. Ordinary remedies failed to relieve. There was pain along the course of the sciatic nerve trunk and its branches, increased on movement and pressure. She was unable to get about. After four injections all symptoms disappeared; the patient expressed herself as feeling just as well as ever. She was under treatment for three weeks.

#### Tic Douloureux.

Two cases of this painful and intractable ailment have been under treatment. In one case the result was completely successful, in the other it was a failure. The following is a brief epitome of the successful case.

*Case 6.*—Male, aged 65. Had always enjoyed good health, except for recurrent attacks of pain over the left eyebrow, which commenced five years previously; at first recurring about every six months, the intervals gradually became less and less. When first seen the attacks occurred every evening about 6 o'clock, persisted throughout the night, and passed off in the early morning, the patient being free from pain during the day. No previous treatment brought any permanent relief, and life was a burden. After four injections the attacks were less severe. After eight injections the attacks still persisted, but the pain was duller and bearable. After twelve injections the attacks, which had been getting less severe and less frequent, ceased. He was under treatment for two months.

#### Facial Neuralgia.

Three cases of so-called facial neuralgia, apparently of rheumatic origin, have been treated—two with complete, one with only partial, success. The former were cured after six injections at weekly intervals. In the latter, treatment was abandoned after three injections had been given.

#### Chorea.

*Case 7.*—Boy, aged 9. Duration, three months. When first seen there were marked involuntary movements of the arms and head, with twitching of the face; there was also a mitral bruit. After four injections the movements ceased. The patient was under treatment for three weeks.

*Case 8.*—Girl, aged 15. Duration, eight years. She had had recurrent attacks. The mental and physical conditions were much impaired; involuntary movements were general. After six injections the condition was much improved. The movements, which were severe, were now reduced to spasmodic twitches. After twelve injections the movements had ceased; her physical condition was good, her mentality much improved. The duration of treatment was three months.

#### Tonsillitis.

These cases occurred chiefly in adolescents and young adults. In all there was a tendency to recurrence in the spring and autumn, and all were accompanied by symptoms elsewhere, which pointed unmistakably to their rheumatic origin. Otherwise there was nothing to differentiate them, superficially, from ordinary subacute attacks of tonsillitis. Treatment was carried out in the intervals between the attacks. Six injections were administered

in each case. Eight remained well for over a year, and the remaining four for periods varying from over six months to a year, all having passed the period at which a recurrence was due.

#### CONCLUSION.

In conclusion, it should be noted that the foregoing remarks are not put forward in any sense as a critical study, but merely represent a brief record of individual experience concerning a certain line of treatment, with its results.

### TREATMENT OF ORIENTAL SORE BY PHOSPHORATED OIL.

BY

ALDO CASTELLANI, C.M.G., M.D., F.R.C.P.,

PHYSICIAN, MINISTRY OF PENSIONS HOSPITAL; LECTURER, LONDON  
SCHOOL OF TROPICAL MEDICINE.

The treatment of oriental sore (dermal leishmaniasis) which I devised some time ago and have used in three cases during the last six months consists in injections of recently prepared phosphorated oil into the nodule and around it.

*Method.*—A sterile 20 minims all-glass hypodermic syringe is used; 5 minims of the oil are drawn in and injected into and around the lesion by inserting the syringe in two or three places into the nodule itself and under the skin around the periphery; if the lesion is ulcerated two or three drops of the oil, in addition, are dabbed on the fundus of the ulcer after removing the crust. The injections are given once or twice a week.

The result in all three cases has been very satisfactory, evidence of incipient healing appearing almost immediately after the second or third injection, and an apparently complete cure being obtained within three weeks to two months.

#### CASE I.

A demobilized army officer, aged 26, contracted oriental sore six months ago in Persia—one large non-ulcerated nodule and a partially ulcerated one, both on the left forearm. Microscopical examination of both lesions showed the presence of *Leishmania tropica* Wright. The patient had had severe malaria and had been treated with large doses of quinine. He had had no treatment of any kind for the sore. I gave him altogether seven injections (5 minims each) of phosphorated oil at rather irregular intervals, as he could not come to see me very regularly. The actual injections were painless; after a few hours there was a slight local reaction, the lesions becoming somewhat oedematous and the surrounding skin slightly reddened. Symptoms of rather severe general reaction occurred once; after the third injection the patient had fever (102°) and felt chilly and unwell, with rheumatoid pains all over the body. The symptoms may have been due in reality to his old malaria, as the temperature fell to normal with sweating within twenty-four hours; I could, however, find no malaria parasites in the blood. The open sore healed very quickly within two weeks, a smooth white scar being left; the non-ulcerated nodule took six weeks to disappear.

#### CASE II.

A young married woman (British), age 24, presented on the left wrist a small smooth nodule with a few scales at the apex and no sign of ulceration. Microscopical examination showed it to be an oriental sore, contracted apparently two months earlier in India; the first sign of it appeared during the voyage home. Six injections of phosphorated oil (two a week) were followed by complete disappearance of the lesion within three weeks. The injections were never painful, the local reaction was very slight, and there was never any sign of general reaction.

#### CASE III.

An Englishman, aged 22, had contracted oriental sore seven months earlier in Iraq. There was one very large nodule on the left forearm ulcerated at the top and covered with a thick crust, as positive. The patient said that with intravenous injections of tartar it had also been considered to be of with salvarsan unsuccessfully. He was given an injection of phosphorated oil (5 minims) twice a week into the nodules and at several places under the skin and around it. The lesion took two months to heal completely.

The method seems to have been successful in these three cases, which are all I have treated. The following points should be kept in mind: First of all, it is essential that the phosphorated oil should be of recent preparation; old phosphorated oil is inert. The phosphorated oil I have used is the oleum phosphoratum B.P. The injections are practically painless, but after a few hours there may be some local reaction, the lesions becoming slightly swollen and the skin around them somewhat reddened; apparently severe general reaction is rare; a reaction lasting twenty-four hours occurred after the third injection in Case I, but the patient was an old malarial subject, and the condition—though I did

not find any malarial parasites—may have been malaria, especially as it terminated in sweating.

Phosphorus is a powerful poison, and its delayed action on the liver should especially be kept in mind; it should therefore be given with care, and every precaution taken. I may say, however, that though I have used injections of phosphorated oil in only three cases of oriental sore, I have used this therapeutic method without any ill effects in several other conditions, since I found, some years ago, that phosphorated oil given by subcutaneous injection was almost painless: I have used it, for instance, without any untoward effect in cases of rickets and of osteomalacia, and in certain cases of very chronic malarial cachexia as an adjuvant to quinine and arsenic.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### TRAUMA AND APPENDICITIS.

The two following cases, in which appendicitis appeared to be the result of trauma, came under my care early this year; the injury in each instance occurred on January 2nd.

#### CASE I.

A young woman, aged 19, a field worker, was walking on the outskirts of a wood when she tripped on a stub and fell flat on the ground, but not upon any projecting object. On raising herself she felt sick and faint, but improved as the day advanced, took her evening meal, and slept well. The next day she felt pain just above the right groin, and could not take her food well. The father, thinking his daughter had received some injury from the fall, asked me to call on the following day.

I saw her at 3.45 on January 5th. She had abdominal facies, anorexia, and complained of pain in the right lower quadrant; temperature 103°, pulse 140. There was scarcely any movement of the abdomen, a resisting area in the right iliac region per rectum, and some tenderness on palpation high up.

From the history, I wrote a note to King's College Hospital (to which the patient was admitted) expressing the opinion that she was suffering either from a large hæmatoma commencing to suppurate or an acute appendix abscess.

Operation was performed the same evening, and the following note, from Mr. St. J. D. Baxton, assistant surgeon to the hospital, describes what was found: "She had a localized appendix abscess; it was shut off from the general peritoneal cavity with very firm adhesions, but the abscess was very offensive. I took the appendix away and drained the cavity. I took some trouble to avoid opening the general peritoneal cavity, and hope that will be rewarded, so I do not know if there was any free fluid in that. Your note regarding the fall was very interesting."

#### CASE II.

A farm labourer, aged 59, while standing astride a wooden pole slipped and fell, his whole weight coming on the lower part of the abdomen. He felt sick and faint, and went home. He resumed work the next day, and continued to work daily until January 8th. On this day the district nurse was called in; she decided that it was necessary the patient should see a doctor without delay. He was seen by Major S. H. Smith, who ordered enemata to relieve constipation, and a mixture for what was diagnosed as a reflex asthma. That night the nurse reported no result from the enemata, and proposed giving a high one. This was agreed to, and a request was made that a report on the state of the patient should be submitted early the following morning. No report came, and the patient was not visited again until January 12th. He had commenced to vomit the previous night (mucus and bile), complained of pain in the right inguinal region, and had had no action of the bowels since the high enema on January 8th. The abdomen was immobile and distended.

The patient was removed to Gravesend Hospital on the afternoon of January 12th, and operated on in the evening. A report from Mr. G. R. M. Cordiner states that "his abdominal cavity was found to be full of foul-smelling pus. On search being made, a gangrenous perforated appendix was found."

Farningham.

T. F. HUGH SMITH.

#### FOREIGN BODY REMOVED FROM THE ORBIT.

Mr. W. was taking an inebriated friend home, a misplaced kindness, which resulted in a severe blow causing a wound below the left eye. Next morning he consulted the local medical man; who stitched the wound, which healed by first intention. Four weeks later Mr. W. was sent to me, and was admitted to the Salisbury Hospital, Southern Rhodesia. There was a scar below the left lower eyelid, and external and superior strabismus on the left side, the eye being displaced outwards and upwards. There was also extensive herniation of the bulbar conjunctiva, which protruded between the lids and hung over the malar region. The pupillary reaction and tension were normal. There was

marked diplopia. Ophthalmoscopic examination revealed nothing abnormal; the fundus and media were clear. The herniated conjunctiva was excised; there was slight purulent discharge from the wound, which was opened, explored, and drained. Examination showed fracture of the orbital plate (superior maxillary) with displacement of fragments, and fracture of the lacrimal bone, but raised no suspicion of any foreign body. A second operation was undertaken ten days after the first, on account of short recurrent attacks of left fronto-temporal headache of a stabbing character. The orbit was freely exposed by opening and extending the original wound, following the anterior border of the orbital plate of the superior maxillary and malar bones. Fractures in accordance with the x-ray report were found. The sphenoidal fissure was explored, revealing the rough edge of a foreign body, which gave an impression of a fragment of loose bone. This was grasped by sinus forceps, which slipped, and a portion of black material (vulcanite) was noticed on the tip of the forceps. The foreign body was then seized with bullet forceps, the lumen of which contained 1½ in. of vulcanite pipe stem, the broken end of which projected into the brain substance. The broken end being embedded in the brain for about 1.8 in., the mouth end being embedded in the brain to the extent of about 1 in. The edges of the sphenoidal fissure were fractured. The wound was closed, leaving a long drainage tube leading to the brain cavity. The operation wound healed rapidly, and the patient made an uninterrupted recovery. The eye regained its normal position with perfect movement, and binocular vision was restored. The point of particular interest in this case is that definite symptoms were absent until four weeks after the injury.

H. V. GATCHILL, F.R.C.S., D.P.H.

Salisbury, Southern Rhodesia.

## Reports of Societies.

### GASTRIC AND DUODENAL ULCERS.

A joint meeting of the Sections of Medicine and Surgery of the Royal Academy of Medicine in Ireland was held in the Royal College of Physicians on February 2nd. The President of the Surgical Section, Sir WILLIAM I. DE COURCEY WHEELER, who was in the chair, said that the Council of the Surgical Section had arrived some time ago at the conclusion that it would be advantageous to arrange co-operation between that Section and the Medical Section. The latter had from time to time invited or accepted communications from individual surgeons, and leading members of the General Council of the Academy had been taken by the General Council of the Academy to approve the principle of joint meetings and definite action had been taken by the physicians and surgeons, and the result was the meeting now held to discuss the diagnosis and treatment of gastric and duodenal ulcers.

In opening the discussion the President said that there might usefully revolve. Often the presence of a gastric ulcer could not be definitely ascertained unless an accident such as perforation occurred, or deformity produced by cicatrization is put beyond doubt by an x-ray picture. In cases of duodenal ulcer without deformity he had frequently obtained two x-ray reports in the same case which at first sight appeared contradictory. One report would state that there was pyloric spasm, some dilatation of the stomach, and gastric stasis; the next report that the pylorus was open and that the stomach contents were shot through by the action of a hypertonic gastric muscle. These apparent inconsistencies could easily be explained when it was remembered that pyloric spasm frequently disappeared when the patient was put to bed on restricted diet and took alkalis freely. The spasm passed off, but the stomach remained hyper-tonic and the contents were readily and forcibly propelled through an open door. It was therefore necessary to take into consideration whether a patient was at work without restriction or in bed under medical guidance. In the small acute ulcers of females he did not think that x-rays were helpful, and he did not think either that these cases were suitable for surgical interference. He was of opinion

that the presence of excess of hydrochloric acid in the stomach was not a characteristic sign of gastric ulcer. It appeared to occur frequently in the absence of ulcer, when pyloric spasm was well marked; but when ulcers were present in the region of the lesser curvature an increase in the amount of hydrochloric acid was not usually found. It was a fallacy to rely on the absence of hydrochloric acid in cases of suspected malignant disease. In half the cases where carcinoma arose primarily, or was grafted on a pre-existing ulcer, the presence of hydrochloric acid could be found; and, on the other hand, achlorhydria was sometimes but not frequently a feature in cases of ulcer of the duodenum. The significance of haemorrhage was all-important. They were all familiar with the haematomesis of biliary cirrhosis; gastric haemorrhage occurred frequently from pathological conditions of the pancreas, gall bladder, appendix, and Fallopian tubes, and other organs, without any lesion in the gastric mucous membrane. Oozing of blood from the stomach had been described by Hale-White under the term "gastrostaxis." In renal disease it was not an uncommon symptom. He believed that it was seen during attacks of gastric crises in tabes. Capillary oozing or bleeding from arterioles quite commonly took place in all these conditions. Under the term "toxic gastric haemorrhage" many such a gastric lesion were at one time thought to be examples of vicarious menstruation. The question of perforation needed passing mention. It could not be mistaken. The patient could tell to the moment when the catastrophe occurred, and could generally indicate exactly the position of the perforation. He never repelled the suggestion of immediate operation, and if he was not an alcoholic he became rapidly anesthetized with ether, and never resented the fumes by a single movement. If the patient came for treatment some hours after the perforation, the shock had passed off, and he would apparently be better. The improvement probably coincided with the outpouring of the protective and defensive fluids of the peritoneum, which had been so vividly described by Murphy. Then the final stage came, with the facies hippocratica, the black vomiting, the pulse quickened, and the temperature rose. Lastly they got the clammy, bright-eyed, toxic patient described ruthlessly by Murphy as being "more fit for an undertaker than a surgeon." The chronic recurrent ulcer needed surgical intervention, and if there had been haemorrhage before the operation there would be duodenal ulcers, and 8 per cent. of gastric ulcers, unless more than gastro-enterostomy was done. Ulcers were now, if possible, excised or destroyed with the actual cautery by Balfour's method. It was his own practice to burn them out. The greatest difficulty that arose at present was the knowledge that perhaps 40 or 50 per cent. of chronic ulcers in people past middle life changed their character and became malignant. He did not believe that gastrectomy was the operation of choice in cases which were known to be non-malignant at the time of operation, but in the hands of Moynihan and Sherren the operation did not carry increased mortality. In special cases he preferred gastrectomy, the first of which he published in 1910. Once gastro-enterostomy was performed the patient again became a medical case, and with proper dieting and the administration of alkalis for three months the results would be very different from those obtained in patients allowed to go their own way.

Sir JOHN MOORE said that the President's paper raised questions which were of equal interest to physicians and surgeons. He would like to know if the symptom of disappearance of pain after taking food was reliable as differentiating a duodenal from a gastric ulcer. He suggested that when giving alkalis in connexion with hyperchlorhydria it was desirable to add a solution of bismuth and ammonium citrate.

Dr. SPEARES said that personally he had never got much help from x-rays in either gastric or duodenal ulcer cases, and though he always had the patients radiographed he did not place much confidence in the results. Regarding alkalis in duodenal ulcer and gastric ulcer, he usually confined himself to Sippy's powder; it had always had good results. A duodenal ulcer presented peculiar difficulties. He would like to know in those cases where there was a perforation of the duodenum if it was necessary to do a gastro-enterostomy. Physicians met with a number of cases of gastric ulcer which yielded readily to medical treatment and did not require surgical intervention at all, but if there was any

suspicion of malignancy, or if the symptoms did not yield to treatment, operation should always be undertaken.

Dr. HARDMAN confined himself to the points on which radiographers tried to base their diagnosis of gastric or duodenal ulcer. The diagnosis of ulcers depended upon direct evidence and indirect evidence.

*Direct evidence:* (1) Niche, or ulcer crater; (2) accessory pocket; (3) organic hour-glass deformity.

*Indirect evidence:* (1) Spastic manifestations—(a) incisura, (b) spasmodic hour-glass, (c) diffuse gastric spasm; (2) retention; (3) hypotonus; (4) localized tenderness; (5) limited mobility.

Certain diagnosis could be made from direct signs. Of the indirect signs, the spasmodic hour-glass was the most important, and was an almost certain sign of ulcer. Other secondary signs alone were sufficient to justify a diagnosis, but if correlated with clinical and laboratory evidence diagnosis might be made much more certain. Belladonna or atropine would differentiate between the intrinsic and extrinsic types of spasmodic hour-glass. The spasmodic type, when intrinsic in origin, was just as important from a diagnostic standpoint as the organic. Spasmodic hour-glass of extrinsic cause was not common, but might be due to a duodenal ulcer, gall bladder disease, or appendicitis. When due to duodenal ulcer the spasm would not be relaxed by belladonna. Pseudo hour-glass stomach might be caused by contraction of the abdominal muscles, pressure of stomach against spine, adhesions, bands, atony, or gas in colon. Duodenal ulcer was more difficult to diagnose radiographically than gastric ulcer. The direct sign was deformity of duodenal contour. Indirect signs were alterations in gastric tone, in peristalsis, and in mobility, gastro-spasm, localized tenderness over cap. The first three signs were an indication of duodenal irritation, and might be associated with conditions other than ulcer; they had often been found in association with mobile colon, with gall stones, and with appendicitis. Taken in conjunction with a typical clinical picture, these were strongly suggestive of duodenal ulcer. If hyperactivity of stomach were found in association with retention and an enlarged stomach of normal outline, the diagnosis was almost certain.

Mr. SETON PRINGLE was of opinion that in diagnosis of gastric ulcers, x-ray reports were of the greatest help. Duodenal ulcers were different, as their clinical history was much more definite and the diagnosis could be verified much more directly. His treatment for gastric ulcer was: if small—cautery excision, and gastro-enterostomy; if large and in body of stomach—knife excision, and gastro-enterostomy; if large and in pyloric portion—pylorotomy. He was of opinion that gastro-enterostomy alone could cure some cases of ulcer in cardia. His treatment for duodenal ulcer on the anterior wall was cautery and gastro-enterostomy. If difficult of access he closed the pylorus by using round ligament as ligature and made a gastro-enterostomy. In gastric ulcer cases, he mostly based his diagnosis on the effect of medical treatment, and in duodenal ulcer on nocturnal pain. Tenderness and haemorrhage were fallacious signs.

Dr. R. J. ROWLETTE said that in practice it was often necessary to make a diagnosis of gastric ulcer without an x-ray report or an operation. Unless the art of diagnosis was bankrupt, they must make practical diagnosis of cases which fell short of absolutely demonstrated certainty, and it was, he thought, of cases like this that physicians had most experience. Regarding diagnosis, he had obtained a good deal of help from x-ray reports, and he would be very sorry to be deprived of the help of the radiologists. Very often cases which had no haemorrhage and no perforation got well by medical treatment, the chief part of which, in his opinion, was rest. Recurrence might take place, but that was liable to happen after operation also. He would be interested to know if many cases of gastric haemorrhage had proved fatal, as he thought that must be an extremely rare occurrence.

Mr. McCONNELL said it did not seem possible that an ulcer could be diagnosed on the clinical symptoms alone. He had seen several patients who had been operated on for duodenal ulcer, and at the operation no ulcer was found, but there was always something wrong with the duodenum; these were examples of duodenal irritation. X-ray reports had been of the greatest benefit to him in dealing with these cases.

Dr. HAYES remarked that x-ray examination was only one method of establishing diagnosis, and the radiographic report should not be regarded as conclusive evidence. There should

be more intimate co-operation between the physician or surgeon in charge of the patient and the radiologist. It was unfair that a diagnosis should be made on the radiologist's written report without a consultation between the doctor in charge and the radiologist.

Mr. STONEY thought it important to do a gastro-enterostomy at the time when operating for perforated duodenal ulcer. He had formerly thought that gastro-enterostomy added considerably to the danger of the operation, but experience did not confirm this view, and when gastro-enterostomy was performed the recovery was quicker and more complete than when it was not done. After gastro-enterostomy the return to feeding should be very gradual. Dr. W. M. CRORTON did not think that x-ray reports were any aid to diagnosis in early cases of ulcer.

## TECHNIQUE OF CAESAREAN SECTION.

A MEETING of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine was held on February 1st, with the President, Dr. T. WATTS EDEN, in the chair, when Dr. S. J. CAMERON read a paper on the technique of Caesarean section.

Dr. Cameron said that his object was to relate briefly the technique which had enabled him to perform 107 successive cases of Caesarean section in rachitic subjects with only one death. It was a decided advantage to have patients under observation for some days before the operation, in order that minor ailments might be treated; for example, special attention should be paid to "colds," as rachitic patients were very susceptible to pulmonary complications after operation. Chloroform was preferable to ether as an anaesthetic. The fatal case in his series died from bronchopneumonia. Perhaps the most important danger to be considered was sepsis. He now performed craniotomy in most patients who had been repeatedly subjected to vaginal examination before admission to hospital, and in all cases where the membranes had been ruptured for longer than twelve hours. The abdominal incision was best made through the right rectus sheath. As regards cases of repeated Caesarean section, where there were numerous and dense adhesions in the region of the former scar or scars, Dr. Cameron thought it advisable not to divide these adhesions, but to avoid them by evacuating the uterine contents by transverse incision in the abdominal and uterine walls. He paid great attention to packing the uterus off from the peritoneal cavity before he opened it. He used two knives—one for opening the abdomen, the other for incising the uterus. He had given up mattress sutures for closing the uterine incision, and now used interrupted sutures of catgut reinforced by three interrupted sutures of silk. He thought the free use of silk within the abdomen was unjustifiable, as, if infected, it might lead to the formation of a sinus. He had seen two cases of uterine sinus or fistula resulting from infected silk sutures. He did not favour the lower uterine segment operation, though it certainly seemed to have diminished the liability to rupture of the scar on a subsequent occasion. It was a difficult operation, and it should be remembered that maternity homes, staffed by general practitioners, were being opened in all parts of the country. Before the patient left the operating-table the surgeon should compress the uterus through the abdominal wall, and if a trickle of blood failed to appear the probability was that a retained portion of membrane was occluding the os; in such a case the index finger should be introduced into the sterilized vagina and forced up the cervical canal.

Mr. BECKWITH WHITEHOUSE and Dr. HENRY FEATHERSTONE read a note on two cases of Caesarean section under spinal anaesthesia with tropacocaine. The first case was one of pregnancy complicated by chronic nephritis and diabetes; the second was one of ante-partum haemorrhage. In both cases the anaesthesia was in every way satisfactory and the result to mother and child extremely good. Three points were worthy of notice: (1) The infant cried lustily as soon as extracted, and presented a very different appearance from that often seen when inhalation narcosis was employed. (2) The tone of the uterus; as soon as the child was extracted the uterus contracted firmly and partly expelled the placenta through the uterine incision. (3) The operation was practically bloodless, due to the tone of the uterus.

Mr. MILES PHILLIPS thought that Dr. Cameron's wonderfully low mortality rate was chiefly due to the wise rules for the selection of cases suitable for Caesarean section.

Dr. J. D. BARRIS thought spinal anaesthesia a good method

in certain conditions such as morbus cordis, diabetes, or pulmonary complications; but the use of morphine was excluded for the sake of the child, and he therefore preferred, in routine cases, to perform the operation under a general anæsthetic.

Dr. HERBERT SPENCER said that Professor Barr had published a series of 97 selected cases without a death—a better series even than Dr. Cameron's. But he thought that both these obstetricians made such a selection of cases as must lead to the unnecessary sacrifice of many children's lives. He saw no reason for refusing to perform Caesarean section when the patient had been examined and the membranes ruptured for twelve hours; so far he had only lost one case of Caesarean section for contracted pelvis, a case already infected at the time of operation, which should have been dealt with by total abdominal hysterectomy, an alternative to craniotomy not mentioned by Dr. Cameron.

#### Clinical Cases and Specimens.

Dr. J. S. FARMAN showed specimens: (1) A necrotic fibromyoma in a patient of 74 simulating cancer of the body of the uterus. The patient gave a history of slight uterine hæmorrhage with offensive discharge for two months. The cervix was atrophic, but the uterus was somewhat enlarged. The cervix was dilated and the uterine cavity explored, and portions of necrotic material came away as the dilators were withdrawn and appeared sufficiently certain evidence of malignancy. The uterus was therefore removed by abdominal hysterectomy. Examination of the specimen showed it to be an innocent polypoid growth made up of cystic spaces lined with endometrial glandular tissue, and it could have been removed quite easily after dilatation of the cervix. (2) A cyst of the uterine cornu due to dilatation of the interstitial portion of the tube. The patient was operated on for an inflamed ovarian cyst, and both Fallopian tubes were found distended with blood-stained fluid. There was also a cystic swelling in the right cornu of the uterus; the body of the uterus was removed, as the nature of the cyst was uncertain. The cyst was found to be lined by tubal mucous membrane and had evidently arisen by blocking of the lumen by inflammation.

Mr. BUCKWITH WHITEHOUSE described a case of adenomatosis vaginae. The patient was a multipara aged 40, who had had constant muco-purulent vaginal discharge dating from a forceps delivery five years ago. Examination showed a very unusual condition of the vaginal vault; the cervix was lacerated and everted, and was the seat of numerous small cysts of the typical Nabothian type which had extended widely to the upper half of the vagina, so that the vaginal vault was completely studded with small cysts, varying in size from a pin's head to a pea. The cervix was amputated, several of the cysts were excised and the remainder obliterated by means of the cautery. The patient was now reported to be free from discharge.

Drs. WHITE-COOPER and H. K. GRIFFITH communicated a case of inversion of the uterus occurring in the third week of the puerperium. There was pronounced inertia of the uterus during labour, which was terminated by forceps and with the help of pituitary extract. There was severe post-partum hæmorrhage in the third stage of labour. On the fourteenth day of the puerperium the patient sneezed several times, and this was followed by bright hæmorrhage from the vagina; at the same time the temperature rose, and during the next two days the patient had rigors. On examination the uterus was found to be inverted. Under an anæsthetic the uterus was reinverted, but the fundus slipped back quickly through the cervix, so the uterus was again replaced and the cavity packed with gauze soaked in flaxine. The gauze was slowly withdrawn, beginning twenty-four hours after the operation, and was completely removed at the end of the third day. The patient made a good recovery.

Drs. White-Cooper and Griffith also reported a case of obstructed labour due to a contraction ring. After the patient, a primigravida aged 32, had been in labour for three days, examination under anæsthesia showed a tight ring of contracted uterus in front of the shoulders, preventing them coming down and preventing also version being performed. Steady traction by forceps failed to move the foetus. It was then decided to perforate and crush the head, then do version and use the breech to dilate the ring; when the crushing was nearly completed the ring was felt to relax and the foetus was quickly extracted by version.

## THE SURGERY OF ABDOMINAL TUBERCULOUS GLANDS.

A MEETING of the Liverpool Medical Institution was held on February 1st, with Professor E. E. GLYNN in the chair, when Mr. G. C. E. SIMPSON read a paper entitled "The surgical aspects of tuberculosis of the abdominal lymphatic glands."

Mr. Simpson said that the acute complications of this condition usually brought the case to the hands of the surgeon, instancing general and local tuberculous peritonitis following rupture of glands, abscess, acute obstruction by bands or adhesions, intussusception, rupture into the bowel, and erosion of the mesenteric artery. He next considered cases complicated by acute and chronic appendicitis, chronic obstruction with serious gastric sequelae and tuberculous infection of the bowel, and gave illustrative cases. He pointed out that enlarged glands might lead to strangulated hernia either by entering the hernia sac and mechanical obstruction, or by causing acute tuberculous peritonitis and leading to oedema and adhesion.

He then discussed the symptoms associated with tuberculous of one or of a few groups of abdominal lymphatic glands apart from complications. He quoted one case of hæmaturia cured by removal of a large calcified gland (alluding to Thomson-Walker's work), and three cases of hæmatemesis among others with less striking symptoms, cured apparently by removal of calcified glands. He also referred to a case of chronic constipation apparently due to tuberculous glands along the vessels of the colon, cured by resection of glands and ascending colon *en masse*, and in another case by resection of the same with three feet of the terminal ileum. A number of cases were mentioned with recurrent abdominal pains where no causative lesion other than tuberculous glands were found, and which improved after resection. In one case of a solitary gland without abdominal symptoms, the gland was 1½ inches in diameter, very caseous and presenting under the peritoneum without any attempt at limiting adhesion. The complicated nature of the operation where many adhesions or a large abscess was present, the unsatisfactory outlook after short-circuiting even if combined with evacuation of the abscess, and the high frequency of serious complications led the speaker to plead for earlier surgical attack on the glands. In such cases the operation either of enucleation or of resection of glands and involved intestine was safe and only called for patience.

Mr. Simpson quoted 57 cases: about equal numbers showed acute complications, chronic complications, and no complications. Twelve cases were over 30 years of age, twelve under 10 years, twenty-one between 10 and 15 years, and twelve between 20 and 30 years. Removal of glands was done in 43 cases, and of these 15 showed no recurrence and three had not been traced; two cases showed signs of abdominal tuberculous. In one case short circuit and scraping out of a large abscess was done in March, 1920, and the man was still at work, but had ascites. Three cases had phthisis; two had died. In fourteen cases in which removal was not attempted two died, two had phthisis, and eight were cured.

On these results he based the following conclusions: (1) Guided by the condition of the patient, operation for the relief of acute and chronic complications of tuberculous glands in the abdomen was not complete unless not only the gland directly involved but any other group infected was removed. In widespread cases where eradication was impossible, it might be advisable to remove glands over which the peritoneum was thinned. (2) Many chronic abdominal symptoms were directly due to tuberculous glands, and removal of these was indicated where other causes for the symptoms could not be found. (3) Even in the absence of symptoms tuberculous glands, and more especially caseous glands, should be removed whenever the condition of the patient allowed. This was a question of prophylaxis, and was as much indicated as the division of bands or of a normal appendix during laparotomy for other conditions.

Mr. W. H. THOMPSON commented on six of his cases in which abdominal tuberculosis had necessitated operation for acute intestinal obstruction. In one where perforation and massive destruction of intestine compelled him to do resection, the patient died. In four cases where involvement was so extensive and the condition of the children so poor, his zeal was limited to combating the obstruction by short-circuiting the bowel. All these cases recovered and were apparently well. As such seriously ill cases had done so well he adopted the same treatment where the general condition

might have permitted a more radical operation; the result was equally satisfactory. Knowing how intolerant children were to intra-abdominal liberties he believed that in such severe cases the operation of necessity, usually lateral anastomosis, ought to be the operation of choice.

#### Ergotism.

Mr. R. E. KELLY and Dr. W. J. DILLING read a note on a case of ergotism with gangrene of the toes. Mr. Kelly said that it occurred in a patient aged 42, a Polish Jew, who had used rye bread for many years. Dr. Dilling tested the bread and flour from which it was made and found evidence of infection by the ergot of rye. Dr. Dilling detailed his pharmacological examinations. He discussed the life-history of *Claviceps purpurea* in cereals and grasses grown on damp, clayey soils during wet seasons. The chief symptoms of convulsive and gangrenous ergotism were mentioned, and the possibility of mild cases being diagnosed as gastro-enteritis was pointed out. Tabular statements showed the rapid loss of toxicity in ergot on keeping and the adulteration (1 to 10 per cent.) in various epidemics. Cases were quoted showing the difference in susceptibility of individuals even in the same family, and an instance of 0.2 gram ergot a day causing gangrene was given. In the present case the evidence in favour of regarding it as an instance of gangrenous ergotism was as follows: (1) The man ate exclusively rye bread, in which mycelial tissue was found microscopically, and extracts representing 46 grams and 88 grams of bread produced distinct cyanosis of a cock's comb; rye from the mill contained 0.1 per cent. sclerotia, and the rye grains were also partially infected; an extract of the ergot caused tonic contractions of an isolated

The patient's two attacks occurred when the ergot of the previous c. (3) There was no haemorrhage on removing the toe. (4) The patient's age, the absence of general arterio-sclerosis, and of extension of the gangrene, were all in favour of this consideration. As no further instances could be traced the case had to be regarded as one of idiosyncrasy.

Professor BRIGGS quoted past clinical opinion against ergot; the pharmacologists were now in search of the best ergot. For many years he had pleaded for closer association in teaching schools between the pharmacological laboratory and the hospital; for example, lists of hospital cases and the drugs used were quite as important as the present familiar long lists of operations. He remarked that the joint report read that nothing on the pathological condition was not incontestable and stimulated similar efforts.

#### Myeloma of the Ischium.

Mr. G. P. NEWBOLT read a note on myeloma of the ischium treated by gouging and radium. Mr. Newbolt described a case of myeloma involving the tuber ischii and extending upwards towards the acetabulum and forwards along the ramus towards the pubes. The patient was a man, aged 47. X-ray photographs showed the extent of the disease. At the operation the growth was freely gouged out. A few days later a tube containing 105 mg. of radium was left in the main cavity for twenty-four hours, and in the cavity of the ramus for a second twenty-four hours. Four years had passed and the patient remained quite well. Dr. C. TRUSTAN HOLLAND showed x-ray photographs which he had taken of the condition before and after operation, and he described the bone changes characteristic of the condition.

#### ARTIFICIAL LIMB FITTING.

At a meeting of the Aberdeen Medico-Chirurgical Society held on February 1st, with the President, Dr. ALEXANDER OOSTON, in the chair, an address on "The art of limb fitting: a plea for the standardization of amputations" was given by Dr. MIDDLETON COXSON, medical officer in charge of the Orthopaedic Annexe and Limbless Centre, Ministry of Pensions, Aberdeen. From the experience of five years at this centre, with the supervision of some 1,400 cases, Dr. Connors advocated practical reforms in the performance of amputations in civil surgery. Although the surgeon in civil cases had the selection of the site of amputation, there was too often a tendency to conform unnecessarily to the "classical" amputations; in such cases co-operation between the surgeon

and the limb fitter was essential in dealing with the problems presented. War experience had shown that only certain amputations could be fitted with satisfaction to all concerned; other "classical" amputations which had proved impracticable as a limb-fitting proposition should, Dr. Connors maintained, be deleted from the textbooks and relegated to lectures on the history of surgery. He then reviewed the sites of amputations of the extremities most likely to be satisfactorily fitted, the reasons for their selection, and the stumps which had proved unsatisfactory. He also referred to the great importance of education in the use of an artificial limb, holding that the best method was to start the patient, as soon as the stump was ready, with the artificial limb which he was permanently to have, the limb not being finished off until all adjustments necessitated by the shrinkage of the stump had been made. He deprecated the use of temporary legs, plaster pylons, and so forth.

At the conclusion of the paper, various models of artificial limbs were shown by representatives of limb-making firms, and Dr. Connors showed patients who had been fitted with limbs and demonstrated very convincingly their ability to use them to full advantage. A short discussion followed, in which Professor MARNOCH, Mr. ALEXANDER DON, and the President took part. Dr. Connors's suggestions as to the teaching of "classical" amputations were generally supported. Dr. Connors then replied, and on the motion of the President was awarded the thanks of the Society for his lecture and demonstration.

A MEETING of the Bath Clinical Society was held on February 2nd, with Mr. W. G. MUMFORD, the President, in the chair, when Dr. A. B. CLUCKIE read a paper on the differential diagnosis of acute conjunctivitis, acute iritis, and acute glaucoma. He discussed the differential features of these diseases both with regard to objective signs and subjective symptoms, and described the correct methods of measuring the ocular tension and the pitfalls of the wrong methods. Dr. A. B. CLUCKIE also showed a case of orbital tumour. Dr. R. G. GORDON showed a case of Charcot's hip-joint in a case which was probably haematomyelia; he also exhibited a case of rheumatoid arthritis with achlorhydria gastrica which showed in addition signs of early pernicious anaemia and early subacute combined degeneration. Dr. V. M. COATES showed a case of early rheumatoid arthritis with enlarged glands and achlorhydria gastrica, and discussed the importance of the latter sign. Mr. FORBES FRASER showed a specimen of round-celled sarcoma of the breast and a case of probable gumma of the breast; he exhibited also a specimen of a large gall stone which had given rise to very acute abdominal symptoms, and an x-ray photograph of a case with a very large gastric ulcer which gave rise to remarkably few symptoms. Dr. SPENCE showed a blood smear from a case of lead poisoning showing punctate basophilia. Dr. MITCHELL showed a specimen of a calcareous subpatellar bursa. Dr. F. G. THOMSON showed a specimen of a large round-celled sarcoma of the kidney. Dr. PRESTON KING showed an x-ray photograph of a fracture of the body of the fifth cervical vertebra which had developed tuberculous disease or a secondary growth. Mr. W. G. MUMFORD showed a case of severe double talipes, and also a case of old arthritis of the hip of seven years' duration in a child aged 10 showing signs of coxa vara.

THE Medico-Psychological Association of Great Britain and Ireland will meet at the City Mental Hospital, Gosforth, Newcastle-on-Tyne, on Thursday next, February 22nd. The chair will be taken by the President, Professor G. M. Robertson of Edinburgh, at 2.45 p.m. Discussions will be held on the future policy of the Association as regards its nursing certificates and examinations, and also on the appeal for funds for the prevention and treatment of insanity, and the formation of the Council of Mental Hygiene.

THE annual report of the Institute for Medical Research of the Federated Malay States for 1921 has reached us recently. It is compiled by Dr. William Fletcher, acting director of the Government laboratories, and deals in the main with routine work; but a special inquiry was held into cases of malaria described as "quinine resistant." Of 44 such cases investigated, in only one was the condition uninfluenced by quinine; in one other case described as "relatively resistant" parasites persisted for a long time in spite of treatment. It is pointed out that before accepting a statement that a case resists quinine care should be taken to make certain that the drug is being swallowed by the patient.

## Rebels.

## THE SURGERY OF THE WAR.

[FIRST NOTICE.]

In the two volumes which treat of the *Surgery of the War* the editors and contributors have acquitted themselves nobly. To write the story of the surgical achievements which the years 1914-18 cover was a monumental task. One may truthfully say that the surgeon of to-day, once more engrossed in civilian practice, hospital or private, will have his memories vividly awakened by the perusal of these volumes. Clad in their unattractive green backs (why should an "official" book not seek to please the eye and tempt the buyer as much as those issued by private enterprise?) he may pass them by. But though the outside may be rather official most of the inside is thoroughly human and interesting. The print is clear, the paper heavy, and most of the illustrations are admirable, many having been reproduced most faithfully in colour.

It has been said by Bacon that "It is the nature of the mind of man, to the extreme prejudice of knowledge, to delight in the spacious liberty of generalities." It is certainly very natural for the reviewer of a book like this to cloak his remarks in generalities, and he trusts that he will be forgiven if he fails to mention many admirable sections and descriptions.

The first volume begins with a section on projectiles, their varieties, velocities, theories of action, relative sterility and effects on the various tissues. This section, whilst of general interest, will appeal especially to the professional soldier, both combatant and medical.

The destructive effects of shell and bomb bursts in confined spaces are described, and the mechanism by which death follows from explosion without wounding is discussed, but a definite conclusion is not reached. A long paragraph by the editors on the radiating effects of missiles is very much to the point; concrete examples are given of severe injury to underlying soft parts from wounds caused by missiles which struck glancing blows without penetrating deeply themselves. There are two photographs of a slip of German dum-dum bullets. It is doubtful how widely these were used. The explosive action of the standard pointed-nose bullet in the skull was well known long before this war, and in the limbs its pulverizing action on bone was so great that exit wounds at least were commonly of an explosive type. Certainly the soldier himself frequently asserted that he had been hit by an explosive bullet, sometimes adding that he had heard it burst! It was usually difficult to exclude the possibility that the sound that he heard might well have been the impact of the missile on bone. Burns from shell-bursts were not so important in the field as they were in naval warfare, and the great heat generated by large shells fortunately failed to reproduce the conditions described at sea by Surgeon Commander H. E. R. Stephens.

## Wound Shock.

We turn next to the chapters on wound shock. Shock remains one of the *bêtes noires* of surgery, because the surgeon cannot properly explain it, and as a result cannot properly treat it. This statement needs, perhaps, a little qualification, and may seem ungenerous to those who have laboured so well to elucidate it. But it remains that our treatment is still largely empirical, though by no means entirely unsatisfactory. One thing the war brought home to all, and that was the effect of certain anaesthetics in increasing shock, and the value of one anaesthetic—gas and oxygen—in diminishing the chances of producing it. In the short chapter on anaesthesia these considerations are discussed. The apparent improvement under ether anaesthesia and the subsequent rapid collapse of badly shocked men was often a surprise, and spinal anaesthesia, from which we had reason to expect so much, caused too great a fall of blood pressure. Failing gas and oxygen, ether from the Shipway apparatus is cordially recommended. Marshall has pointed out that 54 per cent. of abdominal cases had broncho-

pneumonia with open ether, only 14.7 with warm ether. But it is evident that in abdominal operations, and especially those on the upper abdomen, there is always the question of lung collapse, from immobility and interference with expansive mechanism of the lower parts of the lung, to be reckoned with. This chapter, by Captain H. P. Crampton, should be read by all, though it might have been developed with advantage.

To return to the sections on shock and blood transfusion by Lieut. Colonel Cowell, Captain Fraser, Major Gordon Taylor, and Captain K. M. Walker. It brings us at once to the admirable work which was carried out at the instigation of the Medical Research Council and fostered by it. This body deserves the very highest praise for the work it did, and in these volumes the reader will constantly see traces of its handiwork. Fraser's article on wound shock in casualty clearing stations forms the best synopsis on shock with which we are acquainted. "The problem of the lost blood" is entered into in considerable detail, stress being laid on the observations of Captain (Professor) Emrys-Roberts on the higher red cell count in the capillary as compared with the venous blood. The Crile-Mummery theory of a primary vasomotor paralysis is dismissed; similarly the excessive storage of blood in the splanchnic area receives no support. The evidence against a splanchnic storage rests on naked-eye observation at operation. But it might well be asked how much reliance can be placed on such a method. One of the outstanding features of shock is pallor of the skin, and yet we are to believe that a large concentration of blood takes place in the capillaries of the skin. If such be the case it occurs to one to suggest that superficial observation of the splanchnic vessels may be an inaccurate method of estimating the volume and concentration of the blood contained within them.

Chromatolysis of the nerve cells of the brain and cerebellum is put down to anaemia and relative deficiency of oxygenation owing to the low pressure. This is an extremely probable explanation and rests largely on the pathological investigations of Mott. Due attention is paid to the histamine shock of H. H. Dale. There is adequate acknowledgement to Henderson for his work on the genesis of acidosis in shock. Cowell's blood-pressure observations under varying conditions of excitement, fear, and pain furnish some most interesting passages. The tracings are of very exceptional interest, and the chapter gives a most lucid and suggestive description of the conditions likely to favour the onset of wound shock, and illustrates also the relation between primary and secondary shock, the influence of anaesthetics on these patients, and the effects of toxæmia. The development of severe shock in lightly wounded men is made clear, and no less so the aggravation of their condition by the rapid onset of microbial infection. In fact, a strong link is forged connecting gas infections with the lowered blood pressure and the sluggish circulation of shocked patients. The influence of injured vessels in inducing gas infection in the muscles of the anaemic territory is brought home by Sir Cuthbert Wallace in a very able chapter. Stress is laid on the importance of avoiding further vessel damage in the excision of the wound. This section is illustrated by some of A. K. Maxwell's beautiful coloured drawings.

There is a good deal of overlapping in the sections hereabouts which makes it impossible to give the various authors their due, for shock, haemorrhage, and infection naturally come within the range of all. Great stress is laid on warmth, sleep, and the giving of fluids (especially hot sweetened tea) in the treatment of primary wound shock. The question of morphine is handled with reservation, large doses being condemned. It is generally admitted that it is harmful in acidosis, and should therefore not be given to cyanosed patients. It is interesting to recall that Crile, who was at one time the high priest of morphine for shock, in his latest writings has somewhat modified his use of the drug. Bayliss's 6 per cent. gum acacia in 0.9 per cent. saline receives more general commendation than we should have expected, as the blood transfusion enthusiasts at one time rather condemned it—not as harmful, but as of little value. This was, no doubt, an exaggerated view, and there can be no doubt about the inefficiency of ordinary normal saline which was the panacea for everything fifteen years ago. How many dying patients had their last hours disturbed by the real life house-surgeon and his miraculous saline! Of drugs, atropine and digitalin receive highest commendation, atropine having a more temporary action. Strychnine, of course, is not recommended.

<sup>1</sup> *History of the Great War, Based on Official Documents: Medical Services. Surgery of the War.* Vols. I and II. Edited by Major-General Sir W. G. Macpherson, K.C.M.G., C.B., LL.D., Major-General Sir A. G. Bowley, K.C.B., K.C.M.G., K.C.V.O., Major-General Sir Cuthbert Wallace, K.C.M.G., C.B., and Colonel Sir Crisp English, K.C.M.G. London: H.M. Stationery Office, 1522. (Med. 8vo, pp. vii + 618 and 604 respectively; illustrated. 25s. each net, post free 26s.)

*Tetanus and Trench Foot.*

Tetanus is dealt with by Sir F. W. Andrewes, and the tables and charts which he uses illustrate the fall in mortality which followed the prophylactic injections. Sir David Bruce's work is freely mentioned. A few cases of local recurrent and late tetanus, always subjects of exceptional interest, are referred to.

The section on trench foot is rather short, but the reader is referred for further information on this fruitful cause of "wastage" to the volume which is to be published on the hygiene of the war.

*Field Ambulances and Casualty Clearing Stations.*

The account of work in the field ambulances and the development and rise of the casualty clearing stations will interest many readers, bringing back recollections of friendships, of work on teams, and of the gradual evolution of the high efficiency which came to mark these units. The amount of work the clearing stations got through was often astonishing: for instance, 30,000 operations were done during the first four and a half months of the Somme fighting; 14,400 men were admitted to thirteen casualty clearing stations of the Fourth Army on the first day, 13,806 on the second, and 8,793 on the third. The total number of wounded on the Somme from July 1st to November 17th, 1916, is stated to have been 318,408. At the battle of Messines, 10,434 wounded were treated in eleven casualty clearing stations on the first day. The effects of early operation were immediately evident, for of these only 0.5 per cent. developed gas gangrene subsequently, and the base hospitals reported a low death rate and few amputations.

The casualty clearing station was an innovation, and no doubt has come to stay, though it is interesting to speculate what shape it might take in a more mobile war than the last. At all events we trust that the lessons learned in this war, and particularly the importance of mechanical as opposed to chemical cleansing, will not be forgotten. Operations must be done early, and every facility for the carrying out of the necessary treatment must be provided as close as possible to the firing line. In future wars, unless an international arrangement is held to, advanced operating stations may be driven underground by aircraft.

*Wound Treatment.*

The important subject of wound treatment is discussed by more than one writer, and considerable overlap occurs. There is no doubt that the South African war did our army surgery a great disservice; for it was easy to attribute the relative benignancy of long-range bullet wounds in that campaign to the success of the full use of antiseptics and asepsis. How far this was from the truth we were soon to learn.

Sir George Makins, in his chapter on "Surgery in general hospitals," has a well written review of the various steps in our re-education. Everyone will recall the failure of the antiseptics and will remember Sir Almoth Wright's crusade against chemicals. His ingenious experiments and the attractive physiological character of his explanations gained many adherents. Still, at the bottom of his heart, every surgeon loves an antiseptic, and though you may prove to him that in the case of wounds his chemicals do very little good, he is apt to hug them as being better than nothing. The fact that Sir Almoth Wright had reason on his side was abundantly proved by the improvement which followed the immediate excision of wounds, although Wright's own methods did not find wide favour. The excision method had been in use in this country, here and there, for some years before the war, but it must be admitted that the civilian surgeons who now say they always used it failed to make their voices heard at the proper time. In spite of arguments, antiseptics were used to the end in conjunction with excision, which was always given first place. We wonder how many hospitals are carrying out the principles of complete mechanical cleansing and of excision in their casualty cases to-day, or how many of the smaller hospitals realize how much they can save themselves in the cost of dressings, maintenance, and attendance by insisting on the primary excision of accidental wounds—to say nothing of the economic advantage from the patient's point of view.

Of the various antiseptics of the war those that appear to be surviving best are bipp, flavine, eusol, and the Carrel-Dakin method. Of bipp it may be said that its chief enemies are those who know least how to use it. Of the Carrel-Dakin method it may truly be asserted that though one may know well how to use it the difficulties of

correct application are so great that few who have the knowledge can make good use of it. Of all antiseptic methods it is theoretically the most perfect, but it is certainly the most difficult and the most tedious. It is doubtful whether its disadvantages do not debar it from use on a large scale, and as it needs highly skilled attention it is not a method which can be used on the occasional case, for continued practice with it is necessary. The reader will find all that he wants to know about the various antiseptics in Sir Anthony Bowlby's article on the casualty clearing stations, in the article of Makins already referred to, and in C. J. Bond's excellent paper on the hospitals in England.

*Wounds of the Chest.*

Wounds of the chest are dealt with by T. R. Elliott and G. E. Gask. A tremendous impetus has been given to the surgery of the chest as the results of war experience, and it is something of a relief to find that a very reasonable and conservative view is taken by the authors. No attempt is made to hide the serious nature of these wounds, or the very high mortality that attends them. Most surgeons who were in France in 1918 will remember the very optimistic view that was held by many of the newer surgeons. A few of these allowed their enthusiasm to outrun their discretion, and Gask speaks wisely of the training that is necessary before a man can become a competent chest surgeon. It was an interesting, nay a fascinating, discovery that the chest could be opened without the use of elaborate pressure chambers. True, this was no new knowledge, but it was knowledge shared by the few. It is a thankless task to discover who exactly was responsible for the change that came over surgical practice in regard to thoracic wounds in France. The names of three people will come to mind at once. But whoever he was, a great service was done to the armies. As in the case of the brain, it is impossible to give any accurate data as to the exact mortality of chest wounds on the field. The best results, excluding these immediate deaths, gave a mortality of about 27.5 per cent., or a little less than 1 in 3. Gradually the general principles which were applied to all wounds came to be applied to the chest—to operate early to stop bleeding, to excise the wound and broken bone, to remove lodged foreign bodies. But when applied indiscriminately to all chest wounds, the results were found to be very little if any better than had been obtained by the old conservative treatment.

The great problem in the chest as elsewhere was to combat sepsis, and though the above methods seemed eminently suitable to prevent this dreaded enemy from obtaining his foothold unnecessary operations were being performed with the best intentions, but not always with the happiest results. The turn came when it was laid down that blood effusions without evidence of serious intrathoracic injury were to be treated on conservative lines. An excellent account is given by Elliott of the physical signs in these cases and of the need for repeated needleings if infection of the blood is suspected. The clinical aspects of the cases are clearly described. Elliott discusses lung collapse in the injured and uninjured side. He is not a believer apparently in the frequent contralateral collapses which some claim to find. No cases of "pleural shock" are referred to. We should have liked to see a dogmatic statement on this point. A short description is given of surgical emphysema. It would have been worth while to have mentioned the very wide distribution of subcutaneous air sometimes found—at the wrists, for instance, on the scalp, and in the scrotum.

Gask's account of the operations of military surgery on the chest wall and lung is clear and well illustrated. The various stages of the operations are well figured. His insistence on aspiration of the chest on the day following operation is good. The various methods of dealing with pleural infection are described. Empyema is undoubtedly a more serious condition than has been generally recognized. It will be remembered that the exceedingly high mortality of post-influenza empyema in the United States of America caused the appointment of an Empyema Commission of Enquiry. There is a good deal of truth in Gask's remark that the surgeons who took the most pains with their infected chests got the best results. This probably accounts for the excellent effects of the Carrel-Dakin method in Tuffier's hands, for this method insists on the surgeon's constant attention whether he wills or no. For persistent pleural fistulae the authors recommend decortication, but they do not describe how this is to be applied to those most difficult and persistent cases of all—those with long, shallow cavities running up

beneath the scapula to the third rib or thereabouts. They mention that in 1920 there were still pensioners suffering from persistent pleural sinuses. We might add that in 1923 they are still with us, though not perhaps all the same patients. These cases present some of the most difficult problems of surgery. The freed lung will not now expand, and the general condition of the patients often makes them the worst possible operative risks.

#### Wounds of the Pericardium and Heart.

Sir George Makins treats of wounds of the pericardium and heart. This is largely a compilation from the War Office collection and from the literature. It is very ably put together, and reads well. The figures illustrate a variety of wounds, some amenable to surgery, but many not within the possibilities of repair. A point is made of pericardial (and also of myocardial) sepsis, and one wonders whether some apparently brilliantly successful operations would have ended in the death of the patients had a drain been inserted. Major Litter Jones's dramatic case is described in full; here the pericardium was left open. In Sampson's it was closed with success—probably not a good precedent. The reader will find a workmanlike account of the various methods of exposure of the heart and some useful indications for operations.

#### A TEXTBOOK OF MEDICINE.

*The Textbook of the Practice of Medicine*,<sup>2</sup> by various authors, edited by Dr. FREDERICK W. PRICE, will be of great service to the English medical profession. Usually English textbooks of medicine, for students and practitioners, have been written by one author. But since no physician can now claim an extensive knowledge of all of the groups of diseases described in a medical textbook, it follows that generally all sections of such a work, by one author, are not of equal merit. In this volume each section has been allotted "to one author, or to two writing in collaboration, instead of enlisting the services of a large number of writers." Altogether there are twenty-six contributors to the work.

The book commences with articles on fever by Professor Pembrey, and on infection, immunity, and immune therapy by Dr. J. Matthews and Sir Thomas Horder. Most of the fevers commonly met with in England are described by Dr. C. R. Box; the articles on septicaemia, erysipelas, influenza, tuberculosis, cerebro-spinal fever, and rheumatic fever are by Sir T. Horder; those on tetanus, anthrax, glanders, actinomycosis, and hydrophobia by Sir T. Horder and Dr. J. Matthews; and those on spirochaetosis ictero-haemorrhagica and epidemic jaundice by Sir W. H. Willcox. Typhoid fever is described by Lieut.-Colonel Byam, leprosy by Dr. C. R. Box, and acute anterior poliomyelitis and lethargic encephalitis by Drs. J. Collier and W. J. Adie. The article on syphilis is by Colonel L. W. Harrison. Tropical fevers and tropical diseases generally (in all sections of the book) are described by Dr. G. C. Low, and are treated more thoroughly than in any other English textbook of general medicine we recall.

This first portion of the book is of great value and interest, since it contains, in a concise form, the experience of writers who have devoted special attention to the diseases they describe. Dr. J. Collier contributes the articles on caisson disease, anoxaemia, and sea-sickness, and Sir W. H. Willcox those on heat-stroke, alcoholism, poisoning by arsenic, lead, mercury, and food poisoning. Dr. J. Matthews describes the bacteriology of food poisoning. A concise account of gout, obesity, and diabetes is given by Dr. G. Graham, who apparently recognizes the limitations of the starvation treatment in diabetes.

Rickets and scurvy, and also epidemic diarrhoea in children, are described by Dr. R. Hutchison. The relation of the sympathetic nervous system to endocrine glands is considered by Dr. Langdon Brown. The suprarenal thymus, thyroid, and pituitary glands are described by Dr. O. Leyton.

The articles on diseases of the digestive system, liver, gall bladder, pancreas, and peritoneum are (with five exceptions) by Dr. A. F. Hurst, who gives us a concise summary of his own experiences, and of his valuable work on x-ray examination in these affections. Acute intestinal obstruction, appendicitis, and peritonitis are described by Mr. E. G. Slesinger. The accounts of diseases of the lymphatic system, blood, and spleen are by Dr. Hugh Thursfield.

<sup>2</sup> *A Textbook of the Practice of Medicine*. By various authors. Edited by Frederick W. Price, M.D., F.R.S., Edin. Oxford Medical Publications. London: H. Frowde, and Hodder and Stoughton. 1922. (Demy 8vo, pp. xxiii + 1753; 95 figures. 35s. net.)

The interesting section on diseases of the heart is written by Dr. F. W. Price (with the exception of one article). It shows the great advance in cardiology made in recent years, and is illustrated by eighty-six tracings and electro-cardiograms. Progress in the treatment of cardiac diseases is less evident. Sir T. Horder contributes a valuable article on infective endocarditis. The articles on disease of the arteries and veins, on thrombosis, embolism, and aneurysm are by Dr. T. Thompson; the relation of aneurysm to syphilis is emphasized. The section on diseases of the lungs, pleura, and mediastinum are by Drs. R. A. Young and G. E. Beaumont. The summary of the recent work on the causation of lobar pneumonia is of great interest. The affection is regarded as an acute infectious disease, and the authors advise that "if possible, no case of pneumonia should be nursed in a general ward of a hospital, and the doctor and nurse in attendance should wear gauze masks." Concise accounts of the various diseases of the nose, larynx, and pharynx are given by Mr. H. S. Barwell. This summary will be very useful in general practice.

Diseases of the kidneys are described by Drs. W. Langdon Brown and G. Evans. We are glad to note that in addition to the various forms of nephritis causing albuminuria, another group of cases is recognized—"leaky kidney." The name is not quite satisfactory, since it does not indicate what is leaking, but the authors have done good service by drawing attention to these cases, which are not infrequent in practice. "Leaky kidney" is defined as a "condition in which the kidney leaks, allowing some of the blood proteins to escape; but is not the subject of a progressive lesion as in nephritis." It is the result of some old damage, and may follow acute nephritis. Diseases of the joints and bones are considered by Sir William H. Willcox. A concise account of the various diseases of the skin is contributed by Dr. A. M. H. Gray.

The section devoted to diseases of the nervous system by Drs. J. Collier and W. J. Adie is very thorough. The account of brain tumours is of special interest; but some surgeons will not agree with the recommendation that "No attempt must be made to remove a tuberculoma . . . since any disturbance of its seat results invariably in tuberculous meningitis and death." The account of compression of the cord is excellent, and the great diagnostic value of lumbar puncture in these cases is emphasized. Myelitis is briefly mentioned under myelomalacia; it is often discussed in differential diagnosis; and syphilitic myelitis is described under syphilis of the nervous system; but no separate account is given of acute myelitis, in the transverse or disseminated form. Apparently acute myelitis is regarded as "nearly always of syphilitic origin." The work concludes with a concise section on psychological medicine by Sir Maurice Craig and Dr. E. D. Macnamara.

The book may be strongly recommended to students, general practitioners, and physicians. It is an excellent work, and gives, in a most concise form, a vast amount of valuable information, and the experience of many of the most able London physicians. The system of conjoint authorship has, on the whole, been well managed. In a book containing so great a mass of details it would be easy to pick out statements from which dissent might be expressed; but this would take us too far. The wording of the book is necessarily often very concise, and occasionally this obscures the meaning. The type is small and the paper very thin. In another edition the publishers might consider the advisability of improvements in these respects and might also with advantage encourage the authors to increase the number of illustrations.

#### CYTOLYSIS.

PROFESSOR G. H. ROGER, Dean of the Paris Medical Faculty, in a preface to a book by Dr. Louis Bory on the destruction of cells,<sup>3</sup> recommends it as a guide to laboratory workers on account of the concise information it contains, and to medical men for the practical applications that may be obtained from a study of autolysis.

The first part of the work deals with autolysis—the last act of life—under the two main headings of experimental autolysis *in vitro* and autolysis in the living organism; the

<sup>3</sup> *La Destruction Cellulaire*. By Louis Bory. Preface by G. H. Roger. Paris: Masson et Cie. 1922. (Roy. 8vo, pp. . . .)

latter is divided into physiological autolysis, which is constantly taking place but is so compensated that no histological change or functional disturbance occurs, and pathological autolysis—for example, maceration of the dead foetus *in utero*, cerebral softening, the changes in the centre of tumours, and the effects of radiation on organs, such as the sexual glands, and on new growths. From comparatively recent work by Roger and by himself in conjunction with Garnier the author is inclined to doubt the view of previous investigators that the products of autolysis are highly toxic, and to consider that autolysis rather diminishes the injurious effect of the juices of the organs by lessening their coagulative power. Experimentally, autolysates from half its renal or hepatic substance are required to kill the animal, and as this amount of autolysis rarely occurs clinically it appears improbable that fatal results of this kind often occur in man. On the other hand, the autolysates may damage tissue of the same kind as that from which they are derived; thus slow destruction of one kidney entails the production of cytolytins which may seriously affect the other (sound) organ.

The second and much the larger part of this monograph deals with cytotoxicity under the headings of bacteriolysis, haemolysis, and organolysis. In the section on bacteriolysis anaphylaxis is described as resulting when the toxins liberated by destruction of micro-organisms are not properly neutralized, and a brief account is given of d'Herelle's phenomenon, which that authority, as is well known, regards as due to an intracellular ultramicroscopic organism or bacteriophage. The subject of haemolysis, as being the most familiar example, at any rate, of experimental cell destruction, is considered at length, and full attention is given to the pathological aspects of the process—for example, in haemoglobinuria and in jaundice. The concluding chapter on organolysis contains a summary of what is known on this interesting subject, with a number of useful references.

#### MENTAL DEFICIENCY.

It is not surprising that there should so soon be a demand for a new edition of Dr. A. F. TREDGOLD's work on *Mental Deficiency*.<sup>1</sup> The book is excellent in every respect, and no one who is interested in its subject can afford to be without a copy for study and reference. It is a most comprehensive textbook, and as it is generally accepted as a standard work and has already abundantly proved its worth its contents do not call for extended comment. The present edition has been thoroughly revised. The chapters dealing with moral deficiency, criminal aments, clinical examination, mental tests, and diagnosis have been entirely rewritten; considerable additions have been made to the chapters on psychology, mentally deficient children, and the clinical varieties of primary and secondary amentia; and a number of new illustrations have been added.

The presence of the defective in the community constitutes a serious social problem, and Dr. Tredgold deals with this aspect of his subject in the last chapter of his book. No recent statistics are available showing the number of aments still in need of care and control. The Report of the Royal Commission, 1904, estimated that the total number of persons urgently in need of provision was 66,539, and while the Mental Deficiency Act, 1913, has done something to alleviate the position, institutional facilities are still far from adequate to meet the need. Dr. Tredgold points out that the economic disability, the antisocial propensities, and the rate of propagation of these persons, combine to constitute a problem of a magnitude that no civilized country can afford to neglect, either in the interests of the defectives themselves or in those of the community. The author does not deal exhaustively with the question of prevention, but the few pages he devotes to this all-important problem merit the attention of all who are interested in the welfare of the race. His views on sterilization, segregation, and the regulation of marriage are marked by the common sense, balance, and restraint which characterize all his work. Similar comments are applicable to Dr. Tredgold's lucid treatment of moral imbecility, a subject which he has made peculiarly his own. We can again recommend this valuable book with complete confidence.

<sup>1</sup> *Mental Deficiency (Amentia)*. By A. F. Tredgold, M.D., M.R.C.P., F.R.S.M. Fourth edition. London: Baillière, Tindall, and Cox. 1922. (Demy 8vo, pp. xx + 579; 31 plates. 21s net.)

#### ARAB MEDICINE AND SURGERY.

MR. M. W. HILTON-SIMPSON has published an elaborate and careful study of *Arab Medicine and Surgery*,<sup>2</sup> embodying a kind of native pharmacopoeia; it is founded on his experiences and observations amongst the usually reticent Berber and Arab doctors of the Aures Massif in Algeria. These mountains are on the fringe of the great Sahara, to the north-east of Biskra, and the district was selected by the author in 1912 as one in which he "might reasonably hope to find among its Shawiya Berber inhabitants relics of the past in the shape of arts, crafts, and customs which have long disappeared from the more accessible regions of Barbary before the advance of the successive waves of conquest which have swept over North Africa since the dawn of history." He was fortunate enough to become the friend of many native practitioners, who completely admitted him into their confidence, and thus, though himself a layman, he has been able to collect and arrange an extraordinary amount of information concerning native methods of medical and surgical treatment, methods which are destined soon to disappear with the advent of modern European ideas, in which the natives are beginning to have faith. It is the fatalistic attitude of the natives which has kept Shawiya methods so long alive, even in areas which can be easily reached by skilled European doctors. "Success is due, under God's will, to the skill of the doctor, failure and death to the will of God alone." This point of view is agreeable to the native doctor and also readily acceptable to his fanatical patients, who, moreover, have a dread of amputation, "with its unpleasant consequences in the next world."

The native practitioners in the Aures, with whom the author came in contact, were all men who had definitely studied medicine and surgery. They had been apprenticed to an established doctor, almost invariably a member of their own family, and were all comfortably situated from the financial point of view. Professor Edmond Doutté's assertion that "la médecine ne se distingue pas encore de la magie" may be correct in regard to the neighbourhood of Marrakash in Morocco, but cannot be extended to the Shawiya of the Aures. Belief in magic can, however, be traced in some of the native medical methods. Nearly all the practitioners possess "books, some in manuscript which have been handed down from their fathers, others modern reprints of Arabic authors obtainable in Constantine, Algiers, or, especially, in Tunis." These books are used to some extent as works of reference, though they may be of little value in ordinary practice. The works of three of the authors—Suyuti, El Haj Tlemsani, and Mohammed ben el Haj el Kebir—are apparently concerned as much with magical practices as with medicine. The works of Abderrezag, "the Algerian" (eighteenth century), are perhaps those best known to the modern native practitioners. It seems that the medicine as practised nowadays in the Aures is derived from that of the mediaeval Arabians.

One of the most important surgical operations performed is trepanning. "The native surgeons . . . are unanimous in declaring that injuries resulting from a blow are the sole cause of their favourite operation, which, they assert, is never resorted to for the relief of a malady not so caused, and is not performed as a magical cure in cases of persons supposed to be possessed by demons."

An extensive *materia medica* is alluded to in the book, and the author has taken great trouble to identify the plants used by native doctors. The work ought to interest many besides those specially concerned with the history of medicine.

#### NOTES ON BOOKS.

*Tuberculosis in Infancy and Childhood*,<sup>3</sup> by Drs. J. C. GITTINGS, F. C. KNOWLES, and A. P. C. ASHCURST, is based on a series of lectures delivered at the Children's Hospital, Philadelphia. The lectures were addressed to general practitioners; they deal mainly with the diagnosis and treatment of tuberculosis in early life, and attempt, by special sections devoted to the skin and to surgical affections, to comprehend all the more common sites of the disease. There is a good

<sup>2</sup> *Arab Medicine and Surgery: A Study of the Healing Art in Algeria*. By M. W. Hilton-Simpson, B.Sc. London: Humphrey Milford, Oxford University Press. 1922. (Demy 8vo, pp. viii + 56; 8 plates, 12 figures. 10s. 6d. net.)

<sup>3</sup> *Tuberculosis in Infancy and Childhood*. By J. Claxton Gittings, M.D., Frank Crozer Knowles, M.D., and Ashley P. C. Ashurst, M.D. Philadelphia and London: J. B. Lippincott Company. 1922. (Med. 8vo, pp. iv + 75; 23 figures. 21s. net.)

introduction on general considerations, with a useful historical summary taken from the literature. Unfortunately, however, this part is somewhat marred by the frequent sacrifice of clarity to conciseness, and by the failure to give references to the papers which are epitomized. In the chapter on diagnosis the danger of judging by the nutritional appearance of the child is pointed out; in the early stages there is little or no perceptible change, as is shown by the figures of Sachs, who found the nutritional state to be normal or above normal in 64 per cent. of a given series of children examined. On the other hand considerable importance is attached to a careful study of the temperature—especially of the extent of its diurnal variations. A thorough account of the technique and of the interpretation of the tuberculin test in its various modifications is provided. The main systems of the body are then dealt with in a simple, straightforward manner, and the book concludes with a chapter on general treatment, in which particular attention is directed to the prophylaxis of infection. There is nothing new, practically nothing original, and nothing markedly controversial—nor, we imagine, is there intended to be. As a compact and easily readable manual for general use it ought to supply a need felt by those whose practice makes too extensive demands on their time to allow of careful study of the more voluminous textbooks.

*L'Artériosclérose et son traitement* is the third of the five tomes, all now in a second edition, of Dr. ARTHUR JECKERQ'S *Les maladies de la cinquantaine*, and sets forth a rather startling conception of the relation of gout, obesity, diabetes, and arterio-sclerosis. It is that as a result of dietetic excesses, especially in protein food, the liver rises to the occasion and becomes abnormally active for a time—the stage of hyperfunction; this is succeeded by a phase of disordered function, which passes on into functional impairment and insufficiency. The result is that at about the age of 40 years gout is prone to appear, followed ten years later by obesity, then by diabetes, and lastly by arterio-sclerosis. The author regards gout, obesity, and diabetes, not in the light of ordinary diseases, but rather as protective measures adopted by the organism to prevent the flooding of the blood with poisons which would otherwise cause arterio-sclerosis. When the stage of hyperfunction has developed the liver and kidneys are described as undergoing visceral sclerosis, though the liver, from the paucity of interstitial tissue, shows much less evidence of this change; at about the same time the arterial blood pressure rises, and this is followed by hypertrophy of the middle coat, a process analogous to the visceral hyperfunction; on this supervenes a widespread fibrosis of the arterial media. The author considers that this arterio-sclerosis is essentially distinct from chronic arteritis and atheroma, which affect the inner coat and are due to infections and intoxications of various kinds. These hypotheses, which do not appear convincing and are admittedly in opposition to the views commonly held, are developed in the first part of this volume; the second part is devoted to the treatment of arterio-sclerosis and its various complications and is on more conventional lines.

Professor T. B. JOHNSTON'S book on *Regional Anatomy*<sup>1</sup> is a contribution to the Students' Synopsis Series. It is intended for the student revising his anatomy in the dissection room prior to examination. The author in his preface states that he is catering for the ordinary examinations only, and that consequently minor details and long accounts of unimportant structures are omitted. The more important facts and relations are emphasized by the use of italics. The old terminology is used throughout. The section on the central nervous system contains eleven diagrams. The descriptions of organs, structures, and relations are clear and concise, and in a review of a synopsis can more be said? This book should prove really useful to the student doing his final spurt.

*Endocrine Glands and the Sympathetic System*<sup>2</sup> is a translation by Dr. F. RAOUL MASON of the book by Lereboullet, Harvier, Carrion, and Guillaume which formed one of the thirty-two parts of the big treatise edited by Sergent, Ribadeau-Dumas, and Babonneix. This part was reviewed in our columns in March, 1921 (p. 463). A few footnotes have been added by the translator, with the collaboration of Dr. D. R. Ayres. The work of translation has been well done, and the general get-up of the volume is good—better, indeed, than that of the original.

## SEX AND SCHOOL COURSES.

### CONSULTATIVE COMMITTEE'S REPORT.

"Men and women have existed for centuries, but either sex is still a problem to the other—and indeed to itself; nor is there any third sex to discriminate dispassionately between the two." That is a sentence in the introductory chapter of a report prepared by a Consultative Committee appointed by the Board of Education to advise on the differentiation of the curriculum for boys and girls respectively in secondary schools, of which a preliminary notice appeared in our issue of January 20th. The report is one of the most interesting and illuminating documents upon an educational subject that we have read. Moreover, anything that touches the cultivation of the finer attributes and instincts of the sexes is of paramount importance; and school life is gradually extending its influence upon our children with a corresponding diminution of home influence.

The importance of the subject is only equalled by the difficulty attending the answer to the problem set to the Committee; and it has done well in this respect, if alone, for it has shown how many and how disturbing are the cross currents which need to be taken into account before any final determination can be arrived at. The difficulty of these cross currents is so great that in the one type of schools from which a conclusive answer might have been expected there is no answer. The protagonists of equality of the sexes who carry their belief to its logical conclusion have secured the establishment of not a few co educational schools both for day pupils and boarders; from these, if anywhere, one might have expected a clear account of the likenesses or differences of boys and girls in their work, their play, and in the reaction of the sexes upon each other in these respects. But in the appendix dealing with these schools no satisfactory answer is found. The co-education school system appears to have been mainly approved by the men witnesses, the head masters of the schools, for the chiefs of these schools are almost always men; criticism came largely from the women witnesses. The report does not indicate what particular cross current is responsible for this diversity of opinion, but it would seem that even here vested interest—the importance of the headship of a large mixed school as against the headship of a smaller department of a school—produces a very natural bias.

#### *Evolution of the Secondary School Curriculum.*

The report makes it clear that no satisfactory judgement on the present position of secondary education can be arrived at without a knowledge of the past history of education in this country. To meet this need a complete chapter has been devoted to the history of the curriculum in secondary schools. It appears from the preface that this is largely if not entirely the work of Mr. R. F. Young, and for this he justly receives the special thanks of the Committee. The account shows how great an influence opinion has had upon the work of schools. "The development of secondary education, more especially in girls' schools, has been influenced by successive currents of social opinion." In the early part of the nineteenth century the work of the public schools and grammar schools for boys was almost entirely literary—Latin and Greek grammar and versification. Attempts to expand the curriculum of the grammar schools was checked when Lord Eldon ruled in the Court of Chancery that it was illegal for the Governors of Leeds Grammar School to expend the endowment funds in teaching modern and commercial subjects. But the demand for such subjects caused them to be taught as extras, or "accomplishments," for which separate fees were charged. The Non-conformist academies established in considerable numbers from about the year 1662 provided a remarkably wide curriculum, even to the inclusion of natural science—chiefly physics. "These private schools had many faults and weaknesses, but they were more receptive to new ideas and more ready to experiment than the old foundations, and subsequent reforms in the curriculum can be traced largely to their influence." The movement spread to the endowed schools in the early part of the nineteenth century, with Butler at Shrewsbury, followed by Arnold of Rugby, Tailor at Thring of Uppingham. The foundation of a number of proprietary schools by bodies of shareholders gave an impetus to reform, and many of these newer

schools are now well known public schools. The influence of private enterprise was great; indeed, Sir Joshua Fitch reported in 1866 that in Yorkshire "almost all the educational enterprise of the last few years has originated with private teachers." The influence of the introduction of the examination system is also shown to have been at first advantageous in widening the curriculum. Simultaneously games and physical exercises were developed, school societies and other corporate out-of-school activities sprang into existence, so that "the boys' curriculum was already becoming rather heavy at the period (1860-1875) when it was adopted with some minor modifications as the model for courses in the new girls' schools."

#### *Progress of Female Education.*

In the girls' school up to this date the work was mainly devoted to "accomplishments." Sydney Smith, writing early in the last century, says: "The system of female education as it now stands aims only at embellishing a few years of life which are, in themselves, so full of grace and happiness that they hardly want it, and then leaves the rest a miserable prey to idle insignificance." And this was a costly performance, for fees at one of the fashionable girls' schools in Brighton were £500 a year! In general it may safely be said that the traditional education for girls up to about 1845 accentuated the differences between the sexes.

The movement for the better education of girls and women may be said to have begun in 1843 with the foundation of the *Governesses' Benevolent Institution*, which was designed to provide a system of examinations and certificates for governesses. This led to the establishment of *Queen's College*, Harley Street, and the leaders of the movement, such as the Rev. F. D. Maurice, took over the boys' curriculum which they knew, and handed it on to the women's college. Miss Beale and Miss Buss will always be regarded as the pioneers of the new girls' schools, and they were trained at *Queen's College*. There were no ordinary women, as the well known couplet of their pupils shows. Miss Buss, the sterner of the two, boldly threw out, so far as she could, "accomplishments," and made the curriculum of the North London Collegiate School, which she founded and brought to success, as nearly like that of the boys as possible. In evidence she gave in 1865 she said "she did not think that a girl's education should differ essentially from that of a boy in the same rank of life with regard to the subjects which were to be taught, though it was rather difficult to ascertain what was the proper education for a boy." Miss Beale followed much the same lines, with a leaning to milder measures, for she retained the old-world accomplishments in her school at Cheltenham, and recognized the importance of art, for she was a friend of Ruskin. Thus the theory of the emancipation of women seemed to work out on a theory of imitation. The main causes of the assimilation of the girls' curriculum to that of the boys are summarized under three main heads: Humanistic—on the belief that "nature has given to girls equal capacities with boys for acquiring the greater part of that knowledge which is comprised in our higher education." Vocational—on the ground that "every lady is or must be a teacher of some person or other, of children, sisters, or the poor." Economic—in the aim of fitting women to earn a living.

But the influence of parents was inevitable; accomplishments were not allowed to be banished; science, mainly botany, was added owing to the favouring influences of the Sciences and Arts Department, and later domestic subjects were introduced. So that the curriculum, already too full for the boys, became more than overfull for the girls.

Vicious consequences of three competing Government departments in education led, in 1899, to the formation of the Board of Education. The Board enunciated a policy which aimed to secure "a certain measure of breadth and richness in the curriculum of secondary schools, and to leave them a larger freedom in devising and executing schemes of education of their own." The task set to the Board's Consultative Committee is the natural consequence of this policy. It asks: "Should boys and girls study the same subjects in secondary schools? Should they study all subjects in the same way and up to the same standard? And if any different treatment is desirable, what should the difference be?"

At the outset the Committee found one difference: "It seemed to be implicitly assumed that girls' schools, in addition to giving their pupils a general education, should also give them some training designed to fit them for the duties of home life and of motherhood." There is a compulsory provision in

girls' schools of practical instruction in domestic subjects (such as needlework, cookery, laundry work, housekeeping, and household hygiene) which are in practice generally substituted for the wood-work and metal-work taught in boys' schools. For girls over 15, domestic subjects may be substituted partially or wholly for science and for mathematics other than arithmetic.

It appears that the substitutions allowed for the domestic subjects does not relieve the strain on the girls. There was evidence that girls are much less able to protect themselves against overpressure than boys, who have, as a rule, a habit of "healthy idleness," whereas girls are more conscientious. As one witness expressed it, "If you give a girl too much to do she breaks down; if you give a boy too much to do he doesn't do it." It was further found that the curriculum both for boys and girls was modelled too much with regard to preparation for university and professional examination and failed to provide sufficient contact with practical life. Girls, being more receptive than boys, absorbed the knowledge without giving thought to it, so that on entering into work they were found not to have acquired the habit of thinking and acting for themselves and correlating such knowledge as they possess. The assiduity of the women mistresses was held to be partly responsible, for they helped their pupils too much. There is evidence, too, that the curriculum drawn up by the school authorities to comply with the existing regulations was unduly rigid, and did not allow adequate scope to head mistresses to meet the needs of pupils who deviated from the ordinary type. There was also a tendency to overwork the girls at games; this was partly due to the zeal and conscientiousness of the games mistresses, who were sometimes inclined to supervise and direct too much. Stress is laid on the cultivation of remedial gymnastics, particularly for girls, amongst whom postural defects are common.

#### *Physical and Mental Differences.*

Considering the general physical and mental differences between boys and girls and the possible causes of such differences, the Committee points out that though there is a mass of traditional doctrine there is a corresponding lack of precise observation and comprehensive study. But it is now certain that physiological age bears no direct relation to chronological age. Anatomically girls are in advance of boys by six months at 5 years and about one year at 15 years of age. There are material differences in the blood contents—the percentage of haemoglobin is less in the female after puberty; the male is therefore the better prepared for a more abundant liberation of energy with less exhaustion or fatigue. Except in the essential organs of sex other anatomical differences are quantitative and not qualitative. The larger male brain, while closely associated with the larger size of the body, may or may not indicate a better supply of cortical cells or co-ordinating fibrils, or it may only indicate "padding"; but there is no evidence either way. "It is therefore, at present, impossible to infer from anatomical considerations that the average male is potentially more intellectual than the average female." But it appears to be recognized that girls in general are not so strong physically as boys, and are more highly strung and liable to nervous strain. Moreover, medical statistics seem to indicate that there is a higher percentage among girl pupils of cases of anaemia, spinal curvatura, defective eyesight, and minor physical defects; these defects are sometimes caused and often accentuated by sedentary occupations such as needlework.

The periodic disturbances to which girls and women are constitutionally subject condemn many of them to a recurring, if temporary, diminution of general mental efficiency, and these are most intense and pervasive in the critical years of school life. Among the intellectual processes belonging to the higher mental levels there is a difference in memory. In sheer retentiveness, especially in its lower and more mechanical forms, girls seem to surpass boys, and women to surpass men. This difference may possibly underlie the traditional view that women are the more imitative and men the more creative. In tests of ingenuity men seem to be as clearly superior as were women in tests of assimilative power. Experience with research students corroborates the common view that constructive force and initiative came chiefly from the men, while the women students almost without exceptions worked conscientiously and industriously along lines laid down for them. Beyond this little has been determined in any exact fashion, and the Committee concludes that "probably the well known formula that the male was the greater expender and the female the greater conservator of energy

covered all the differences that were not sexual in a narrower sense. It might also account for the greater intellectual vigour and adventurousness with which boys are commonly credited."

But there are other factors to be taken into account. There is a variability within the sexes; within one and the same sex the range of individual variation is, for most mental characteristics, so enormous as almost to obliterate the smaller group differences. These variations are greater in the male, so that the male sex shows the higher percentage of geniuses of almost every type, but also includes the larger number of criminals and mental defectives—an assumption which is supported by evidence that boys are inclined to break away between the upper and lower extremes in most manifestations of ability, while girls keep closer to the norm. Most witnesses agreed that these conditions are not shown until close on puberty, and there was general agreement that the average boy possesses at this age a large amount of physical and mental energy which enables him, as a rule, to surpass girls of the same age. Hence they would protect the girls from overpressure, and some were in favour of actually driving the boy during the period of adolescence.

#### *Sex Differences and School Conditions.*

Differences in response to the subjects of the curriculum are found, but many of these appear to be due to school conditions. Boys do better at classics than girls, for their teachers are the better; contrariwise girls do better at modern languages for a similar reason. Girls do better at English language and literature, for they read more, but they tend to reproduce rather than to reason. Girls know their history and geography facts better, but boys show signs of originality and freshness in their ideas. In mathematics there is a considerable weight of opinion among examining bodies affirming the relative inferiority of girls to boys in work done in this subject; girls show more aptitude for book work than for problems. The Committee is uncertain whether this is a real difference in educability or due to some school conditions or liability to fatigue; but in any case it recommends that girls should drop the subject at an earlier age, and that its teaching should have more practical applications. In science the girls are "microscopic rather than telescopic in their scientific outlook"; boys excel in experimental work, in initiative, in the capacity of judging phenomena, and in reasoning. In music the girls had the advantage of the tradition of accomplishments, the boys the handicap of the breaking voice; but it appears that the girls show a better response to rhythm, which is also observed in dancing. In drawing girls have a high sense of decoration, and under good teachers may draw, model, or paint with the directness of a man many years older and with greater freshness and charm; but the girls' work, highly expressive as it is, is usually based on less sympathetic observation than that of a boy, and is of slighter interest.

Girls suffer at games by over-supervision, and the Committee is of opinion that the authorities of girls' schools would be well advised to arrange their games more on the lines of boys' schools, where the organization of the sports is left very largely to the boys themselves. So with the out-of-school activities there is a tendency to over-organization in the girls' schools. In co-educational boarding schools it generally happens that the boys take, in practice, a larger share of the management of these activities than the girls; the boys also speak more at the debating societies than the girls. It is difficult to compare aptitude for manual work, for the sexes for the most part take different subjects. In a co-educational school the boys had the best gardens, and needlework by the boys was often more particular and exact.

The Committee concludes that "the predisposition of girls to nervous overstrain, especially at the period of adolescence, is one of the most important factors in the problem of female education." The greater liability of the girls to fatigue should be taken into account in arranging the curriculum, more especially in the co-educational day schools. It is interesting to note in this connexion that Miss Beale at Cheltenham had early to change the hours of school, which had been arranged on the plan of the boys' school. On psychological evidence the Committee judges that there is general agreement that girls are more receptive, more imitative, more amenable to discipline, and more conscientious in their work than boys, who are on the whole more independent, unruly, original, and creative. The differences do not seem to justify serious differentiation in the curriculum, except in mathematics and physics. And the pressure of uncongenial

subjects should, if possible, be removed, for a time at all events, when the teacher considers that no further educational benefit is to be got from it.

The Committee points out that there is relative absence of systematic inquiry on the intellectual and emotional side differences between boys and girls of secondary school age in their bearing on education, and urges that research should be undertaken, based on wide deductions over a term of years. Such researches might reveal important facts regarding divergences of interest and differences in intellectual capacity between the sexes at various ages. Similarly, comment is made on the empirical and unscientific character of much of the available evidence on the educational achievements of boys and girls, and systematic inquiries based on experiments should be undertaken in co-educational day schools with a view to collecting trustworthy data.

#### *Some Recommendations.*

Discussing the conflict of home and school duties the Committee does not think it desirable to attempt to divorce a girl's education from her home duties and her home opportunities. No distinction can be drawn between the qualities that go to make a good parent and those that go to make a good citizen; there is a gain in a girl's feeling that her teachers appreciate the dignity of home duties, and have full sympathy with her development in this direction. And no preconceived ideas as to the best preparation, even for motherhood, ought to hamper experiment or to dim vision. All children have to be educated with two ends in view: to earn their own living, and to be useful citizens; while girls have also to be prepared to be makers of homes. Boys and girls should be educated on similar lines, though not necessarily at the same pace, so far as concerns the first two aims. The whole aim should be the cultivation of general intelligence, as distinct from the accumulation of information. Variations there must be in different parts of the country, for a general rule applying to areas so different as London, Gloucestershire, Lancashire, and Durham can hardly fail to do violence to the facts. Each area should work out its own solution of the problem in accordance with its own needs and traditions. In general, girls should have an additional year before sitting for the first school examination. There should be a wider range of subjects, more accomplishments, a lessening of university influence, greater freedom for the teaching of vocational subjects, and less home work, seeing that they have home duties; also organized games in boarding schools for girls should be materially diminished.

On the whole, the Committee is disposed to think that in many schools, and more especially in girls' schools, the daily life is over-organized. The obvious result of such methods is to produce girls and boys who, though well informed, are rather dull, and lacking in initiative and freshness of outlook. This is a serious defect, and steps should be taken to allow boys and girls, but more especially girls, more free time in which to develop their own individual interests.

The report closes with a series of appendices, of which the third and the fifth are of chief importance from the medical point of view. Appendix III gives a digest of certain points in the evidence relating to co-educational day schools (mixed secondary schools). There is here a marked conflict of evidence. The head masters of these schools were favourable to them and urged the beneficial effects upon both sexes; for the most part the women witnesses were unfavourable, to the extent of stating that "the curriculum was arranged for the boys, the school was run in their interests, and, in general, they acted as a depressing element on the girls." Most agree that no harm results in a mixed school up to the age of 11 years; then there should be separation. Serious difficulties arise in staffing, and particularly from the habit of girls to form sentimental attachments—sometimes for a particular teacher. Appendix V is a very able paper by Professor J. G. Adami (to which we alluded in our previous note) on anatomical and physiological differences between the sexes. Full weight is there given to the physiological effects of the endocrine glands, a subject which is insignificantly known to the laity. The story of the "free-martin," there given and explained, is a parable applicable to the alleged influence of the co-educational school.

As we have already stated, this report is one of singular interest and importance, and we hope that the desire of the Committee to secure detailed scientific information upon many of the points raised in the course of the inquiry may bear fruit without delay. It is a fine field for investigation, full of interest, and likely to prove of real profit.

SATURDAY, FEBRUARY 17TH, 1923.

## ACIDOSIS AND ALKALOSIS.

UNDER the somewhat forbidding title "The Acid-Base Equilibrium of the Blood" the Medical Research Council has just published a Report\* dealing with the vexed questions which centre round the words "acidosis" and "alkalosis." The report is by the Council's Haemoglobin Committee, of which Mr. Barcroft is chairman, and a number of well known physiologists and representatives of clinical medicine, members. The report consists of two parts, of which the first is entitled "The blood considered as a fluid"; by this is evidently meant that it is the reaction of the plasma alone that is of direct importance. The first section of this part deals with nomenclature and its physico-chemical significance. An admirably clear account is first given of the significance of "hydrogen ion concentration," of the "buffering" to changes of reaction in blood, and of the manner in which the red corpuscles increase the buffering of the plasma. This is succeeded by a discussion of the words "acidosis" and "alkalosis." The Committee proposes to abolish the use of these words, substituting "ketosis" for the condition in which acetone and its related organic acids are present in excess, and "acidaemia" and "alkalaemia" for conditions in which the blood is abnormal towards the acid and alkaline sides respectively. Probably the use of the word "ketosis" will be found useful, since there is no necessary connexion between acidosis and the presence of excess of acetone bodies; but the rest of the proposal seems unfortunate and unnecessary. The references to the original identification with acidosis of the symptoms leading up to diabetic coma are misleading. It was not the presence of acetonuria (which had been known for long), but the close resemblance between the characters of the urine and the breathing in threatening diabetic coma and in acid poisoning that led to the search for, and discovery of, abnormal acids in the urine and blood by the experimental pathologists who made the discovery; and they had the best of reasons for concluding that it was acidosis, and not merely ketosis, which they had discovered. These reasons are still valid. "Acidosis" and "alkalosis" are, moreover, better terms than "acidaemia" and "alkalaemia," since the latter suggest that only the reaction of the blood is affected, whereas the whole of the body is involved. The abolition of the old terms would help neither clinicians nor physiologists, and might easily cause misunderstanding. It is to be hoped, therefore, that this proposal will be dropped.

The rest of the section deals mainly with the bicarbonate content, so-called "alkali reserve," and "titration alkalinity" of the blood. The real significance of these values from the standpoint of acid-base equilibrium is pointed out, though it is to be regretted that there is not a clearer account of the error which may arise when they are taken as measures of the blood's alkalinity. Thus in the alkalosis produced by anoxaemia, as well as in the acidosis of diabetic coma, they are diminished, while in the acidosis produced by true  $\text{CO}_2$  poisoning, as well as in the alkalosis from ingestion of excess of alkali, they are increased. During the war there were many mistakes in diagnosis, gently hinted at in the introduction to the report, owing to misunderstandings in this direc-

tion. Diminution in the "alkali reserve" or "titration alkalinity" was quite commonly taken as clear evidence of acidosis.

The second section refers very shortly to methods of obtaining blood samples, and the third deals much more fully with methods of measuring or indirectly estimating the hydrogen ion concentration or reaction of blood. The principles of the hydrogen electrode method, together with the difficulties in applying it to blood, and the best method of avoiding these difficulties, are first described. This is followed by a description of the alternative, and, in its latest form, much easier, "indicator" method. In view of the probable small errors owing to slight variations in technique, etc., it is wisely pointed out that relative results are almost as valuable for most purposes as absolute results. The indirect method on the principle introduced by Hasselbalch is then described. This is at present very popular, particularly in America. There seems no doubt that, as applied to blood plasma in a test tube, it gives correct results. Whether it is equally reliable when applied in connexion with that extremely leaky test tube, the vascular system, seems somewhat doubtful. The last method discussed is that of estimating changes in reaction by observed variations in the dissociation curve of oxyhaemoglobin. Round apparent results by this method there is also a good deal of doubt.

The fourth section deals in detail with the buffering of blood. A truly head-splitting diagram (nomogram) devised by Professor L. J. Henderson is included in it. The first part ends with a short, but interesting, discussion of the buffering of the tissues, and particularly muscle. Reading between the lines of this section it is easy to see that acidosis means vastly more than mere acidaemia.

The second part of the report is rather unfortunately entitled "The relation of changes in the hydrogen ion concentration of the blood to pathological conditions of the body." What this part really attempts to treat of is the physiology and pathology of regulation of hydrogen ion concentration in the living body. The first section deals with the recorded values for hydrogen ion concentration of normal human arterial blood under resting conditions. It is clearly pointed out that although different methods give very appreciably different results, yet those by any one method are extremely close to one another—so close that it is not possible to deduce from the measurements that real differences in hydrogen ion concentration exist at different times, though it seems probable that there are very slight differences in different individuals. On the other hand, slight apparent differences have been found by several methods to exist shortly after fairly heavy muscular exertion, while quite large differences have been clearly demonstrated by Dale and Evans in animals after injection of alkali into the blood, though the breathing was still active.

The second section has the unsuitable heading, "The central mechanism of respiration," for it discusses the relations between breathing and the hydrogen ion concentration of the arterial blood and other factors. The development of the experimental work which led up to the conclusion that the rate of ventilation of the pulmonary alveoli in man depends under normal conditions on the hydrogen ion concentration of the arterial blood is first clearly traced. A minute excess or deficiency of hydrogen ion concentration, caused by slight excess or deficiency of  $\text{CO}_2$  in the blood, immediately acts on the respiratory centre and causes an increase or diminution in the breathing, so that no more than a very slight variation of hydrogen ion concentration can be produced. It is also pointed out how the kidneys and the varying production of ammonia in the body co-operate in this regulation. The calculated differences in hydrogen ion concentration which suffice

\* *The Acid-Base Equilibrium of the Blood*. Report to the Medical Research Council by the Haemoglobin Committee. Pp. 70. H.M. Stationery Office. Price 3s.

to produce great changes in the breathing, or even to cause apnoea, are so small as to be beyond the limits which can be detected by any of the existing methods for measuring hydrogen ion concentration. The probable importance of very small changes of hydrogen ion concentration in the body, and the difficulty of detecting them by direct measurements rather than by symptoms, can thus be imagined.

A very useful and suggestive discussion follows of the evidence that when changes in the hydrogen ion concentration of arterial blood are produced by other agents than  $\text{CO}_2$  there may be no immediate response by the respiratory centre, or the response may even be the opposite of what might have been expected. It has been known for twenty-five years that although when caustic soda is injected into the blood (which can be done without any injury owing to the efficient buffering which exists) temporary apnoea is at once produced, yet when sodium bicarbonate is injected the breathing is immediately increased, although the blood must be rendered more alkaline. Clear and quite unimpeachable evidence was recently obtained by Dalo and Evans that the arterial blood of animals after injection of bicarbonate does actually become far more alkaline, but apnoea is not produced. The increase of breathing after bicarbonate injection was quite intelligible so long as it was believed that  $\text{CO}_2$  acts specifically, and not simply as an acid, on the inspiratory centre, since in the blood  $\text{CO}_2$  is at once partially liberated from bicarbonate by the action as weak acids of the proteins, including haemoglobin. But why, if  $\text{CO}_2$  acts only in virtue of its acid properties, is the respiratory centre stimulated when the blood, in spite of the presence of more  $\text{CO}_2$ , is actually far more alkaline? The evidence, both physiological and clinical, in favour of the hydrogen ion theory of respiratory regulation is far too strong to be upset; it is suggested that the reason why the respiratory centre reacts promptly to the minutest changes in  $\text{CO}_2$  concentration, but only very sluggishly to changes otherwise caused in the hydrogen ion concentration of the blood, is that whereas  $\text{CO}_2$  penetrates rapidly through the delicate membranes between the blood and living protoplasm, other substances affecting the reaction of the blood penetrate far more slowly. This is well known to be the case as regards the delicate walls of red corpuscles, and quite clear evidence has recently been furnished in plants by Jacobs that  $\text{CO}_2$  penetrates the delicate cell membrane far more easily than various ions.

A very clear and satisfactory account is given of the effects of deficiency of oxygen on the breathing, and of the manner in which oxygen deficiency leads to an increase of the breathing at high altitudes. The next section deals with the reaction of the blood during exercise. The picture presented by this section is confused, and there is no co-ordination with the preceding section, though the possible means of co-ordination seem evident enough. The statement that there is no evidence of deficient oxygenation of the blood during muscular exertion is surprising, for it is well known that there is both direct and indirect evidence for such a deficiency.

The concluding section deals with "the relation of breathlessness to hydrogen ion concentration in pathological states." Diabetic acidosis or ketosis is first considered. The historical review of this subject is defective, and of the conclusions reached we can only say that they are not likely to convince an experimental pathologist. The breathlessness of renal and cardiac disease, and of the condition so familiar during the war under the name of D.A.H. (disordered action of the heart) are then discussed. It is surprising to find no reference to the quite different types of "breathlessness" existing in these different conditions, since the type of breathing always affords a definite clue to the cause of the abnormality.

The abnormal breathing due to acidosis is, for instance, entirely different from that observed in uncomplicated heart cases or in D.A.H. The treatment of this subject is unsatisfactory, and the same is true of much of the chemical evidence quoted, though some of it is very valuable.

The defects of the report, looked at as a whole, are doubtless due largely to the difficulties of securing agreement among the different members of the committee, and the consequent recourse at many points to unsatisfactory compromises. This, however, does not diminish the great value of individual sections of the report; the defects in co-ordination between the different sections are indeed only a mirror of existing divergences of opinion. In any case, the medical profession is much indebted to the Medical Research Council and the members of its Haemoglobin Committee for the preparation of this valuable report.

## THE ANNUAL REPORT OF THE REGISTRAR-GENERAL.

We publish on another page a brief summary of the principal items in the tables of what will be called in future the Annual Statistical Review of the Registrar-General, from which will be seen that, on the whole, 1921 was a year of favourable mortality experience. Of the great causes of death, cancer alone is increasing, and the precise significance of this increase cannot be determined without a further analysis of the statistics which we cannot now undertake, especially as the age distribution of the population enumerated in 1921 does not appear to be available—presumably a consequence of the delay in taking the census, as the corresponding information was published in the Annual Report of the Registrar-General for 1911.

This first instalment of the vital statistics of 1921 differs in so many respects from its predecessors, the Annual Reports of the Registrar-General, that a few reflections upon the change will not be out of place. One change—the inclusion with the statistics of mortality of the return of notified cases of diseases—is an unalloyed benefit, and will be welcomed by all medical users of the reports. Another—the reversion from folio foolscap to royal octavo—will not be unanimously approved, because in some of the tables it necessitates the employment of a rather less legible type; but an octavo volume is so much handier than a folio that we think this change also will find a majority of supporters. Some other modifications—for instance, the omission of certain small areas but a slightly extended list of causes tabulated for areas retained—have a good deal in their favour.

But, on balance, we think the new method of presentation inferior to the old. One obvious defect in the actual tabulation is the omission of rates of natural increase. Table 1 should certainly have included the total annual births; were space a primary consideration the ratio of standardized rates of mortality on males and females could have been spared. Even the total number of births for the year of record is only to be found on page 62, and no comparison can be made with previous years. This illustrates the inconvenience of paper dichotomies, attempts to define rigidly what is and what is not of "medical" interest. It is not, however, a very important matter; what we do think important is the separation of Dr. Stevenson's review of the vital statistics of the year from the body of tabular matter.

The Annual Report of the Registrar-General of England and Wales has been for more than seventy years a document of unique scientific importance. It has gained this position owing to causes rather characteristically English which it will be interesting to consider. It has

always been the rule of this country to make non-technical administrators heads of departments; as Macaulay said, "From the Book of Dignities a curious list might be made out of Chancellors ignorant of the principles of equity, and First Lords of the Admiralty ignorant of the principles of navigation, of Colonial Ministers who could not repeat the names of the Colonies, of Lords of the Treasury who did not know the difference between funded and unfunded debt, and of Secretaries of the India Board who did not know whether the Mahrattas were Mahometans or Hindoos." The same rule has applied to minor offices, and the choice of the Registrar-General has never turned upon statistical qualifications. But, almost by an accident at the foundation of the office, a medical statistician of great genius was associated with the Registrar-General in a minor official capacity, and, thanks to the good sense of his official superior, Farr did perform all the scientific functions of the office. Even in those paragraphs of the old reports which were signed by the Registrar-General the hand of Farr can easily be detected, while the annual letter bore his signature.

The tradition has continued down to our own time. Ogle's work—despite certain improvements—was not perhaps, as a whole, of the same standard as Farr's; for that of Dr. Tatham and Dr. Stevenson, without making a suggestion which they would certainly repudiate, a suggestion that it is precisely on the same plane as Farr's, can properly be claimed that it has always reached the standard of scientific research work. Such studies as, for instance, those of Dr. Stevenson on the alleged increase of cancer or on the factors of infant mortality would have been welcomed by any scientific statistical journal or learned society in the world. But it is of the essence of genuine research work that it shall have a personal element; nobody can ever hope to reach a great truth without risking a serious error. The man who plays for safety makes very few runs. When any document is clothed with "official" authority the temptation to take refuge in safe generalities is great. By the happy accident of the old system at the General Register Office individual initiative was saved by the expedient of combining in a single publication the personal conclusions of Farr, or one of his successors, and the whole corpus of data. The personal conclusion might be dubious, but there was the whole material upon which it was based for the private investigator to treat if he pleased in another way, leading perhaps to another conclusion. We think this a satisfactory arrangement, and one that should, at all costs, be maintained. On that ground we deprecate the separate publication of text and tables, even if the separation means that the tables are issued a few months sooner.

### RADIUM IN CANCER OF THE TONGUE, OESOPHAGUS, AND RECTUM.

Last year Mr. Hayward Pinch, the Director of the London Radium Institute, in presenting his report for 1921, after giving statistics of all the cases treated, devoted the greater part of the space at his disposal to a discussion of the value of radium in the treatment of various gynaecological conditions. Encouraged by the approval this plan received, Mr. Pinch has this year followed the same policy, and has on this occasion devoted particular attention to carcinoma of the tongue, oesophagus, and rectum—diseases for which radium treatment is very frequently sought.

It will, we believe, generally be admitted that surgery has not been so successful in dealing with these conditions as to arouse any great enthusiasm for it as a method of treating cancer in these positions. At the same time it is obvious that from the curative point of

view alone radium is still not a competitor, as the director of the Institute is emphatic in his statement that operative interference is advised and urged in every case in which it is considered to be at all possible, and radium treatment is restricted to those cases which are totally inoperable, or in which operation is definitely refused by the patient. Notwithstanding the really great results which can sometimes be obtained in these inoperable cases—the general relief of symptoms, the special relief of pain, the destruction and disappearance of masses of growth, the prolongation of life—it is still evident that the fear of delaying operation is paramount in our minds and, as much as anything else, prevents a trial of radium in many cases of early growths in which much might be expected. The newer methods of radium treatment, especially in carcinoma of the tongue—namely, the burying of radium or radium emanation in all parts of the growth in addition to the irradiation of the whole lymphatic area involved—are a great advance in technique, and when combined with the use of diathermy in the first instance give much better results than were formerly possible. The condition of patients suffering from this disease is peculiarly trying, and the pain they experience so bad, that any method of treatment which can hold out fair hope even of relief is not to be lightly put aside because it does not also include a hope of cure. Carcinoma of the oesophagus, again, is a most distressing and altogether hopeless disease; not only is it impossible to hope for cure but even relief of symptoms is very difficult to obtain, and it is disappointing that the results which were hoped for and even expected some years ago when radium was first used for this condition have not been realized. The condition is much more frequently to be met with in the x-ray department of a large general hospital than is generally recognized; in fact, the workers in such an x-ray department come to look upon it as a comparatively common disease. Of the cases applying to the London Radium Institute the site of the growth is at the cardiac orifice in 53 per cent., but we notice that only four cases were seen during 1922; we learn that the experience in Liverpool, extending over many years and amounting to several hundred cases, suggests that the middle third of the oesophagus is the common site. The most that is now claimed for the radium treatment of cancer of the oesophagus is that, to quote the report, "in favourable cases the patient is enabled to swallow food in comparative comfort for six, eight, or twelve months, or even longer, though sooner or later the exposure will have to be repeated." This statement is hardly satisfactory, as it says too little and seems to infer too much. Does it mean that at the end of the period of relief further radium treatment will bring about another period of several months' relief of symptoms, and so on? Patients may live for twelve months or so from the first onset of symptoms without radium treatment, and periods of marked improvement in swallowing may occur without any kind of treatment; in some instances these periods have been fairly long. It would be of interest to know the longest time any patient has lived in an undoubted case treated by radium. The evidence at present available falls short of establishing the proposition that the use of radium in these cases is definitely indicated.

Three ways of treating carcinoma of the stomach by radium are described: In one the abdomen is opened, radium tubes are buried in the growth for twenty-four hours, and the laparotomy wound is then closed. In the second the stomach is irradiated from the interior by passing radium tubes into the stomach through the mouth and oesophagus. In the third method radium is applied from the outside. With a knowledge of the size of the stomach, and the size and positions of cancerous

growths affecting it, and the obvious difficulty of bringing the radium into apposition with such a growth and at the same time protecting the healthy mucous membrane, the second of these methods—namely, the swallowing of the radium tube—appears to be somewhat fantastic. The difficulties of treating an accessible growth are so obvious from this report that it is difficult to imagine that any successful result could be expected in the case of a malignant growth of a hollow organ like the stomach by means of a tube of radium more or less let loose in its interior. It is perhaps to be regretted that that portion of the report which deals with the symptoms and diagnosis of carcinoma of the stomach was not more cautiously worded; many of the statements made will, we fear, be apt to mislead. It is strange that no mention is made of the value of an x-ray examination of the stomach; it is most important, and in diagnosis a reference to it would have made this portion of the report more accurate and of more value.

It is well known that operative procedures in carcinoma of the rectum, provided the patient applies for treatment early in the disease, give fairly favourable results. This suggests that even in the inoperable cases radium might be more effective than it is in carcinoma in other positions. The report bears this out, inasmuch as improvement is reported in sixteen cases treated during the year. Apparently a drawback to the treatment is that the rectal mucosa is, as a whole, very intolerant to irradiation; there is a danger that intractable proctitis may be set up, a condition trying both to the patient and the medical attendant. A point urged in the report is that when the condition is such that the major abdomino-perineal operation is necessary and the patient is 60 or over, then radium therapy, which can often prolong life in comparative comfort for from four to six years, is preferable to operation. This may be true in the case of some patients, but age alone should not be the determining factor, as many patients of 60 or even over are comparatively young.

Many other conditions are alluded to, and, taken as a whole, the report is written with commendable care and restraint; it furnishes a very fair idea of what can be expected from radium treatment, carried out by an expert of long experience with a sufficient amount of radium at his disposal, in a disease which is baffling in the problems it presents, and, apart altogether from its inevitably fatal results, so often means years of misery from the various symptoms to which it gives rise.

#### VISION AND EVOLUTION.

On January 29th Professor Elliot Smith gave the third of his series of Montgomery lectures, dealing with the general subject Vision and Evolution, at the Royal College of Surgeons in Dublin. In the first of this series, which was given in December, 1920, he discussed the problem of the reconstruction of man's pedigree for the purpose of determining exactly what changes occurred in the brain at each step in the progress of man's ancestors toward the attainment of human rank. Before the commencement of the Eocene period in a particular group of primitive tree-living mammals the importance of vision and the extent of visual representation in the cerebral cortex (already increased as the result of arboreal habits) became further enhanced, and this was responsible for bringing the Primates into existence. The continuance of this process led to the still further enhancement of vision in one subdivision of the Prosimiae known as the Tarsioidae, one member of which, the Spectral Tarsier, has persisted in Borneo, Java, and elsewhere from Eocene times until the present with practically no change. The importance of *Tarsius* in this investigation is that it represents the branch of the Prosimiae in which vision for the first time became the dominant sense, definitely displacing

smell as the chief guide of the animal. The sub-order Tarsioidae has the very important significance that it represents the group from which the apes and man were derived, so that the comparison of the brain of *Tarsius* and the most primitive monkeys enables us to determine what was the nature of the process which led to the origin of the higher Primates. Professor Elliot Smith made use of the observations of the living *Tarsius*, and of photographs by Mr. W. E. Le Gros Clark, F.R.C.S., who also sent him from Borneo most of the material for the research. In the second lecture, which was given in January, 1922, the significance of the acquisition of true stereoscopic vision was discussed; the monkeys, it was explained, came into existence when one particular group of Tarsioidae acquired the powers of stereoscopic vision. The development of these higher powers of vision acted as a most profound stimulus to almost every part of the cerebral cortex. The visual area itself became further enlarged and more highly specialized, mainly for the purpose of establishing more abundant and more intimate connexions with the other cortical areas, as well as with other parts of the brain. But the change which was most noteworthy was the sudden expansion of the pre-frontal cortex, and this was due primarily to the development of a much wider range of conjugate movements of the eyes and a further development of the power of convergence. The ability to focus the two images of an object with exactitude on corresponding parts of the retinae prepared the way for the development of the macula lutea, so that the animal acquired the ability to appreciate more fully the nature of objects on the outside world, their exact position, their form, size, and texture. This stimulated the animal's curiosity to examine and handle things, which not only led to the cultivation of the sense of touch and the acquisition of higher powers of skilled movement, but also enabled the animal to train its powers of appreciating form and spatial relations and to learn by experience the meaning of events which were happening around it. This fuller understanding of the outside world gave added importance to information collected by all the senses, even the sense of hearing, and led to the further development of most of the cortical areas. The fixation of vision represents the germ of the powers of attention and of mental concentration in general. In the third lecture, which was given on January 29th, 1923, it was pointed out that the essential factor which enabled these great developments in the cerebral cortex to be brought about was in the last resort entirely dependent upon the acquisition of a wider range of conjugate movement and a much greater control over such movements to give the precision and accuracy which were essential before real vision as we interpret the word could be acquired. The development of these more extensive powers of linking up the movements of the two eyes and acquiring a more precise control of convergence was the result of a very complex series of developments in the brain. They were dependent not merely upon the elaboration of a pre-frontal cortical area, but also upon the transformation of the ocular motor nuclei in the mid-brain and certain other changes in the connexions between both the mid-brain and the cerebral cortex with the cerebellum and the vestibular nuclei. Different aspects of these problems have been elucidated by the investigations of Dr. Wilfred Harris, Mr. Treacher Collins, Professor Winkler of Utrecht, Dr. Brouwer of Amsterdam, and Professor John Hunter of the University of Sydney, and the service which the lecturer tried to render was to correlate the results obtained by these investigators with his own work on the cerebral cortex, and to interpret the respective rôles of the cortex and mid-brain in this process. The wide range of independent movement of the eyes of vertebrates below mammals becomes restricted in mammals when a mechanism for effecting automatic conjugate movements begins to develop. The extension of the range of these linked movements is acquired very gradually in man's ancestors; and the close correlation between the range and precision of conjugate movements and the development of the cerebral cortex is a clear indication of the extent to which our intellectual powers have been built

up on the basis of visual experience. The elucidation of the details of the process requires so many illustrations to make it intelligible that it is Professor Elliot Smith's intention to publish a book presenting the three Montgomery lectures, together with the three Morison lectures on the evolution of the intellect given at the Royal College of Physicians of Edinburgh in 1922, which deal with essentially the same problem from a somewhat different angle.

#### M NERS' PHTHISIS.

DR. A. MAVROGORDATO started the investigation of the effects of inhaled dusts on the lungs in 1913 at Oxford, under the direction of Dr. J. S. Haldane, and with the support of the Medical Research Committee. He has continued the investigation at Johannesburg, and some of his results have recently been published by the South African Institute for Medical Research.<sup>1</sup> The investigation has been carried on partly by experiment and partly by histological examination of the pulmonary lesions in miners' phthisis. Many interesting points have been brought out. It was formerly supposed that foreign particles entered the pulmonary tissues and did harm largely in virtue of their being sharp, pointed, and crystalline; but it is now recognized that in pneumokoniosis the particles are seldom larger than the common micro-organisms, and are taken up by phagocytic "dust cells," and so carried into the lung; they do not get there because of any inherent penetrating properties. Dust that contains silica is harmful, and Drs. Gye and Kettle correlated this effect with the production of silicic acid. Experimentally Dr. Mavrogordato showed the different effects of dusts containing silica and of those free from it. When sterile silica is inhaled it is absorbed by macrophages which manifest "early pleural drift"—that is, they tend to flock to the visceral pleura and form pseudo-tubercles; the silica appears to preserve from autolysis the containing phagocytes, which therefore block up the lymphatics of the lung and form white fibrous tissue; the suggestion is made that lymphatic fibrosis would be a better name than the misleading term "miners' phthisis." Cross sections of the thickened lymphatics resemble pseudo tubercles, and it is pointed out that the early histological changes resemble those in tuberculosis, though giant cells are not formed. It is interesting to contrast the effects of coal dust and silica. Coal dust prevents the fixation of silica in the lung, though experimentally it cannot remove it when once it has got into the lung; it is well known that coal-miners do not develop miners' phthisis. On the other hand, when silica has gained an entrance to the lung and damaged it by interfering with the lymphatic circulation and its power of dealing with coal dust, the carbon accumulates in that region and so accounts for the pigmentation. If, therefore, coal dust or its equivalent were to be employed as a means of preventing silicosis, it would have to be provided at the same time as exposure to quartz dust. There is a most important difference between sterile silicosis as described above and infected silicosis, in which the pulmonary changes are more widely spread, the clinical course much more severe, and the damage not necessarily curable by discontinuance of exposure. Much depends on whether the infective agent is the tubercle bacillus or not. There may be three stages in silicosis: simple irritation, non-tuberculous infection, and finally tuberculous; it is difficult to say in what proportion of cases the infection is first of a non-tuberculous nature and later tuberculous. The old type of disease characterized by cyanosis and right-sided cardiac failure, still familiar in Cornish miners, has become rare in the Rand mines, and early tuberculous infection has become common; with a change in the ...peans to Africans, and in the atmospheric conditions of the mines, formerly dry,

now moist and less dusty, as a result of the application of the wet process work to control the dust. Whether or not the mines have become gravely infected with the tubercle bacillus has not been established.

#### VITAL STATISTICS OF ENGLAND AND WALES IN 1921.

The tables of the Registrar-General's Statistical Review of England and Wales, which have just been published,<sup>1</sup> contain most of the tabular matter formerly issued in the Annual Report of the Registrar-General. In the year 1921, 848,814 births and 458,629 deaths were registered; the death rates, both crude and standardized, are the lowest recorded, being respectively 12.1 and 11.5 per 1,000 persons; the corresponding rates for 1920 were 12.4 and 12.1. Forty years before, in 1881, the standardized rate of mortality was 18.2; in 1891 it was 20 (an influenza year); in 1901 it was 16.9, and in 1911 14.2. In spite of the dysgenic selection due to war, the rate of 1921 is substantially below that of 1911. The rates in age groups at all ages below 65 and for both sexes were lower than or equal to those of 1920. At ages over 45 the improvement is slight, in the first two quinquennials it is substantial. The ratio of deaths under 1 to births, although very slightly in excess of the figure for 1920 (83 in 1921, 80 in 1920), is, with that exception, the lowest ever recorded. This is perhaps the most gratifying feature of all, since 1921 was a record summer, and might have been expected to take a heavy toll of infant life. In 1911—the hottest summer in living memory excepting 1921—the infant death rate was nearly 25 per cent. greater than in 1910—130 in 1911, 105 in 1910. Turning to the causes of death we notice that cancer alone of the chief factors of mortality has increased its hold; the rate of mortality from this cause was higher than in any previous year except 1918, the increase being more amongst females than males. In 1921 cancer was responsible for rather more than 10 per cent. of the total number of deaths, tuberculosis for 9 per cent. In 1911 cancer was credited with less than 7 per cent. and tuberculosis with rather more than 10 per cent. of the whole number. The five great groups of disease forms—heart diseases, cancer, tuberculosis, pneumonia, bronchitis—comprise almost half (46 per cent.) of the total mortality. Regional mortality exhibits the usual features, being higher in the northern than the midland or southern areas. Thus Darlington (12.3) was the only one of the five county boroughs within the geographical county of Durham recording a crude rate of mortality below 14 per 1,000. Of the six East Anglian county boroughs (East Ham, Southend, West Ham, Ipswich, Great Yarmouth, and Norwich), Great Yarmouth (12.9) had the highest death rate. The lowest rate of infant mortality in the Durham county boroughs was 96, the highest in the East Anglian county boroughs 75. In the metropolitan boroughs, the rate of infant mortality ranged from 54 in Stoke Newington to 111 in Shoreditch. The rates of mortality from the principal infectious diseases were favourable. The rate per million persons of enteric fever was slightly higher than in 1920, but less than in any previous year; measles had much the lowest rate of the present decennium; scarlet fever, which was very prevalent, had a lower death rate than in 1920, as had diphtheria. In the whole of England and Wales, 315 cases of small pox were notified; 106 were of persons in the city of Nottingham, 92 in the West Riding of Yorkshire, 40 in Middlesbrough, 16 in Derbyshire, and but 2 in London. Five deaths from small-pox (all males) were registered. The number of deaths attributed to influenza was 8,955, the smallest number since 1917. Malaria was credited with the deaths of 139 males and 4 females; in 1920 there were 240 deaths of males and 10 of females so described. Encephalitis lethargica was returned in 729 cases, a considerable increase over 1920—460 deaths. A new feature of the report is the tabulation of cases of notified infectious disease, which occupies fifty-two pages.

## LOCAL GOVERNMENT AREAS.

THE rapid—in some instances phenomenal—increase in the population of many towns in England and Wales during the past forty years has added greatly to the difficulties of administration, and has created many anomalies. In some cases encircling belts of rural areas have become urbanized but still retain the administration of a rural district, while in others contiguous urban districts have so spread out their suburbs that, meeting each other, it has been wellnigh impossible to define the precise boundaries. An excellent example of the latter is to be found in the Staffordshire Potteries—Mr. Arnold Bennett's "five towns"—which during Mr. John Burns's presidency of the Local Government Board were formed into the county borough of Stoke-on-Trent. In more recent years many applications have been made to the Local Government Board or the Ministry of Health for sanction to extensions. Some of these have been granted and others refused. The refusals have caused much heart-burning in the districts concerned, for the central department did not appear to have any settled policy. In these circumstances the action of the Government will be generally approved in appointing a Royal Commission "To inquire as to the existing law and procedure relating to the extensions of county boroughs and the creation of new county boroughs in England and Wales, and the effect of such extensions or creations on the administration of the councils of counties and of non-county boroughs, urban districts, and rural districts; to investigate the relations between those several local authorities; and generally to make recommendations as to their constitution, areas, and functions." The reference, as will be seen, is wide, and we are glad to find that it includes the investigation of the relations between local authorities and the making of recommendations as to their constitution, areas, and functions. The additional duties which the Legislature in recent years has cast upon local authorities, most of them of necessity requiring the appointment of special officials to carry them out, has resulted in a considerable amount of overlapping and consequent extravagance in administration. All this may be rectified by thorough inquiry and well considered recommendations. Many instances of anomalies might be given. The rural district of Chesterfield, with 76,000 inhabitants, has a larger population than there is in each of eleven English and Welsh counties; the population of Wrexham rural district (63,000) is larger than that in each of six Welsh and three English counties; and the population of the Rhondda urban district (162,000) is only exceeded in two of the Welsh counties, and it is higher than that in eight English counties. No exception can be taken to the constitution of the Commission, which includes representatives of counties, county boroughs, urban and rural districts. The Earl of Onslow will be chairman, and Mr. Michael Heseltine, of the Ministry of Health, Whitehall, S.W.1, secretary.

## QUAKER RELIEF IN STRICKEN EUROPE.

IN these troublous times our view of Europe is apt to be limited by our own immediate wants and difficulties. We remember the Russian famine, but few of us perhaps realize the present state of affairs in the devastated lands of Austria and Poland, as well as Russia. In a film, "New worlds for old," the work of the Relief Committee of the Society of Friends in meeting the crying need of these populations is vividly displayed. In Vienna there was overcrowding in the poorer parts. The Society supplied materials for houses, and the actual building was done mainly free of charge by the people themselves. To remedy the food shortage seeds were given, and to meet the shortage of milk the Society sold cows to farmers, to be paid for in milk. The milk so received was distributed to children and tuberculous patients. The acute distress among the middle classes was not forgotten. Parcels of food were distributed to many whose annual pensions would not at the present time suffice to pay for a week's supply. Many of the women were able to do needlework, which was paid for by the Society in food. The population of the devastated areas in Poland is urgently in need of help. The pictures showed refugees still trekking

back to their homes over the immense snowy plains, sometimes in small sledges, sometimes walking. Often they succeed in reaching their village, only to find that their home has disappeared, and that a young forest of pine trees is growing up on the land which they once cultivated. Their only refuge is often a mud hovel. One such dug-out, 6 ft. by 4 ft., is shown in which a whole family lived with their cow and their pig. Fortunately wood is plentiful, and the Government gives timber for building, while the Society provides tools and transport. The peasant himself does the work, so a house can be built at the cost of £9. Food, clothes, seeds, and implements are all required to start these peasants in life again, but by spinning, weaving, and embroidery they are able to pay for a great part of what is required. Famine conditions still prevail in the Buzuluk district in Russia, for the harvest failed again last year. Medical relief as well as food has been provided, and must be continued till the harvest of 1923 if the district is to be saved. The Society of Friends has kept before itself the ideal that men must be helped to help themselves; the people go back to their natural avocations. In return for their work they receive the necessities of life and the means to restore them to prosperity. Their gratitude is sincere, and the exertions of the Society in the lands where it has worked will not soon be forgotten.

## PASTEUR CELEBRATION.

THE centenary of Pasteur will be celebrated at a social evening of the Royal Society of Medicine on Wednesday, February 28th. The President, Sir William Hale-White, will give an address on Pasteur in relation to medicine, and Professor T. M. Lowry, F.R.S., Director of the Laboratory of Physical Chemistry, Cambridge, will give a short lecture on Pasteur in relation to chemistry. Afterwards Dr. Gustavo Monod will speak on Pasteur as an artist, illustrating his remarks by lantern slides of some of Pasteur's drawings. The French Ambassador does not expect to be in this country at the time, but the French Consul-General will be present. Invitations have been issued to other representative Frenchmen in London, and members of the profession are invited to attend.

DEAN INGE will give an address on a subject relating to religion and medical sociology at the meeting of the Marylebone Division of the British Medical Association which will be held at the house of the Medical Society of London, 11, Chandos Street, on Friday, March 2nd, at 8 p.m. Members of the medical profession who are not members of the Association are invited to attend this meeting.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

## The New Session.

THE King's Speech at the opening of the new session on February 13th, though it did not raise any fresh issues of a striking character, indicated a programme of larger dimensions and greater variety than had been anticipated. To the usual paragraph about the estimates for the public services was appended the observation that the financial burdens of the country were heavy, and that reductions in public expenditure remained essential to the well-being of the State—an intimation, in short, that further cuts are contemplated. Proposals will be made to grant credit facilities to agriculturists, to remove anomalies in local taxation, to deal with unemployment insurance benefit, housing, trade boards, and industrial insurance. Certain of the recommendations of the Committee on the Restrictions of Rents Bill are to be embodied in a bill, and measures will be submitted for simplifying legal procedure, effecting economies, especially in the county courts, and consolidating various branches of the law. From the medical point of view the principal comment in the lobby on this outline of work for the coming session was that directly interests will apparently be indirectly rather than directly concerned in the legislation to be proposed. But the King's Speech is never drawn up to comprehend all that is intended to be done or attempted. Moreover, private members will have greater facilities at certain sittings each week than was the case during the last Parliament.

## England and Wales.

### EAST LANCES (TERRITORIAL) WAR MEMORIAL.

On Saturday, February 10th, an extremely impressive service was held at the Manchester R.A.M.C.(T.) headquarters on the occasion of the unveiling of the memorial to the officers, nurses, and men of the 42nd East Lanes Division who gave their lives in the great war. The memorial takes the form of three canopied tablets with the names of the nine officers, seven nurses, and 177 other ranks placed above a semi-column containing the dedication:

TO THE GLORY OF GOD  
AND IN PROUD AND GRATEFUL MEMORY  
OF THE OFFICERS, NURSES, N.C.O.s AND MEN  
OF THE R.A.M.C.  
WHO SERVED WITH THE EAST LANCES  
DIVISION T.F.  
WHO GAVE THEIR LIVES  
IN THE SERVICE OF THEIR KING AND COUNTRY  
DURING THE GREAT WAR.

It is surrounded by bronze pillars and chains, and is a fitting companion to the memorial to those of the corps who fell in the South African war.

After the inspection of the guard by Lieut.-General Sir John Goodwin, Director-General A.M.S., the hymn "God of our fathers" was sung by the troops and an assembly of about 500 doctors, nurses, V.A.D.s, and Red Cross men who had gathered to do homage to their fallen comrades. Colonel W. Coates, in asking the Director-General to unveil the memorial, referred to the units which had originated in the East Lancashire Division: the 18th Field Ambulance, the first Territorial unit on foreign service in France, September 6th, 1914; the 65th Division, trained here after the departure of the 42nd; the 33rd General Hospital in Mesopotamia and the 57th General Hospital in France; the 64th Casualty Clearing Station; and at home the 2nd Western General Hospital, starting with its 520 beds and developing, with auxiliaries, to over 20,000 beds, which dealt with over 850,000 casualties. The difference in service between the combatant forces and the medical service was emphasized. Personal reference was made to the deaths of some of the officers and to the seventy-five who were drowned in the Aegean Sea.

The Director-General, after unveiling the memorial, mentioned his personal acquaintance with the 18th Field Ambulance and the 66th Division in France, and later referred to the hospital work at home, giving special praise to the Red Cross service, particularly to the transport branch. He concluded his short and direct address by emphasizing that these "without any personal advantage or gain in a spirit of loyalty and devotion served their fellows. That spirit still survives with us, and so long as it does England can never go down." After Canon Scott, the Subdean of the Cathedral, had dedicated the memorial, the buglers sounded the Last Post.

In asking Sir Frank F. Adam, the chairman of the East Lanes Territorial Association, to accept the custody of the memorial, Colonel Westmacott referred to the question of the utility of such mementoes, and said this was placed in position by the comrades of the fallen, not only to recall their memory, but also for those who came after but knew them not as an incentive to them, and as a standard of what must be required of them. After Sir Frank Adam had accepted the custody, and Lieut.-Colonel Callam had offered thanks to the Director-General and others, the hymn "O God, our help in ages past" was sung, and the réveillé terminated a very touching ceremony.

### WELSH NATIONAL SCHOOL OF MEDICINE.

The Royal Commission on University Education in Wales, of which Lord Haldane was chairman, recommended in its report (1918) that the Welsh National Medical School should be a constituent college of the Welsh University rather than an integral part of the University College of South Wales and Monmouthshire at Cardiff. The recommendation of the Royal Commission was not accepted; the medical school has been established as a part of the University College, Cardiff and that college some time ago presented a petition to the Privy Council for a supplemental charter embodying this arrangement. The Court of Governors of the University College had before it on February 8th a letter from the Privy Council containing the following passages:

"Their lordships, after careful consideration of the whole problem, have come to the conclusion that, in order to avoid most of the difficulties inherent in the scheme as it now stands, it will be best to constitute the National School of Medicine a separate constituent college of the University of Wales to be governed, under the University, by a council and senate of its own, as recommended in the report of the Royal Commission on University Education in Wales (see paragraph 216 of report).

"Their lordships are of opinion that not only does the change of plan proposed appear to be the best expedient on the ground that the interests of the school and the college alike would be better served if the school were administered as a separate institution, but that the views of many of the bodies who at the date of the Royal Commission's report dissented from this portion of its recommendations have undergone a substantial modification."

Dr. T. H. Morris (Cardiff) pointed out that there was a good deal to be said on both sides. While it was true that the reports of the Board of Medicine had to be approved by the college council, that body could not alter a report but only suggest amendments. If the two bodies did not agree on any point it had to be referred to the University, which alone had a veto on the Board of Medicine. This, in his opinion, was practically the same thing as making the medical school a constituent college of the University. He moved that the letter from the Privy Council should be referred to the council of the University College for consideration and report. After considerable discussion Dr. Morris's motion was carried unanimously. The council at its meeting of February 9th appointed a special committee to report upon the whole subject.

### THE LONDON RADIUM INSTITUTE.

The London Radium Institute (Riding House Street, Portland Place, W.1) has possessed a small in-patient department since October last. This arrangement permits the combination of surgical procedures with radium therapy, and thus enables radium to be applied in the most effective manner possible in such situations as the treatment of cancer of the bladder. It also makes it possible to administer larger doses in a shorter time. This so-called "intensive radium therapy" has given most encouraging results in lymphadenoma, leucocythaemia, lympho-sarcoma, and mediastinal tumours; but it is recognized that much careful observation and long clinical experience will be required to determine the limits of safety of large doses. Though the phenomena attendant upon the immediate systemic disturbance which follows a heavy dose of radium are well known, the possibility of later consequences, such as interference with the internal secretions, blood changes, and atrophy of the mucous glands, must be constantly kept in mind. A diathermy apparatus of the latest pattern has been installed, as that method is considered to be of value as a preliminary to radium treatment when dealing with extensive fungating growths of the palate, vulva, bladder, and other parts. The exuberant masses are thus completely removed, and subsequent treatment of the base and edges of the growth, with numerous small platinum screened tubes, leads to the degeneration of any isolated scattered foci in the normal tissues and excites a protective fibrosis.

The total number of new cases seen during the year was 804. It appears from the table given that the total number of patients suffering from carcinoma who applied was 305; of these 35 were examined but not treated and 4 abandoned treatment; from 60 no recent report has been received and 20 received prophylactic irradiation only; 16 were apparently cured, including 3 cases of cancer of the breast and 2 of the uterus; 110 cases of cancer were improved and 50 were not improved. The cases of cancer of the breast treated numbered 63; of these 12 received prophylactic irradiations only. Of the remainder 3 were apparently cured, 28 improved, and 10 not improved; 2 died, and from 8 no recent report has been received. The results in rodent ulcer were remarkably good; of 138 cases in which the result could be traced 102 were apparently cured, 34 were improved, and only 2 not improved. Of the miscellaneous non-malignant cases treated it may be noted that of 20 cases of arthritis deformans 11 were improved, and of 7 cases of spring catarrh 1 was cured and 6 improved. With regard to the terms used the report contains the following statement:

"The column 'cured' refers only to cases of a non-malignant nature, as it would be unjustifiable to claim as 'cured' cases of malignant disease which have been treated for the first time during the past year.

"The term 'apparent cure,' used in relation to cases of malignant disease, must be interpreted as representing a condition in which all trace of the original lesion or lesions has disappeared, in which there is no sign of any recurrence, and in which the patient is, so

far as can be determined by a thorough and careful examination, free from any indication or symptom of the disease.

"Cases have been classed under the heading 'improved' only when the result of treatment has been to produce a definite and marked degree of benefit, either in the direction of retardation of the progress of the disease, diminution in the size of a growth, healing of ulceration and arrest of hæmorrhage and discharge, or of relief to such subjective symptoms as itching, tenderness, pain, dyspnoea and dysphagia."

Altogether 8,620 treatments were administered during the year, of which 4,165 were given free of charge to necessitous patients.

The demand for the loan of radium emanation apparatus has increased so much as to be an important part of the work of the Institute: the number of such applicators prepared during the year and distributed to hospitals and medical practitioners was 887. Advice is freely given to any medical practitioner on the treatment of disease with emanation, and if precise information is furnished as to the nature and extent of the disease or growth suitable apparatus with full instructions is usually sent within two or three days. It is found that in the case of patients of very advanced age, enfeebled constitution, crippled condition, or suffering from disabilities of any kind which prevent them from journeying to London, effective radium treatment can often be successfully given at the patient's home by his own medical attendant, by the use of emanation apparatus of appropriate strength and suitably screened.

Of the patients suffering from malignant disease who attended the Institute the condition in the majority was inoperable, so that the prospects of obtaining even an apparent cure were slight. No case, however, is refused if there is believed to be any chance of improving the patient's condition, lessening pain, and prolonging life. In a few such cases the results have exceeded the most sanguine anticipations.

The body of the report is devoted to a consideration of radium therapy in diseases of the alimentary canal and its accessory glands. It is, in fact, a monograph on this subject and is likely to be as much appreciated by the profession as was the similar essay on radium therapy in gynaecology published in the report for 1921. Particular interest attaches to what Mr. Pinch has to say about the radium treatment of carcinoma of the tongue, oesophagus, and rectum, and to this matter we refer at some length elsewhere (p. 297).

A brief report on the Research Department is contributed by the Director, Dr. J. C. Mottram. The results of the researches in which he has taken part have already been published in the *Proceedings of the Royal Society* and in the *British Journal of Experimental Pathology*. A report by Mr. W. L. S. Alton, F.I.C., Director of the Chemico-Physical Laboratory, contains an illustrated account of the apparatus used at the Institute for the preparations of emanation applicators by a chemical method, which will be demonstrated to persons interested who will make an appointment with Mr. Alton at the Institute.

## Scotland.

### PROPOSED PRESENTATION TO DR. MATTHEW HAY.

A LARGE and influential committee has been formed for the purpose of presenting Professor Matthew Hay, M.D., LL.D., medical officer of health for the City of Aberdeen, with his portrait or bust in recognition of the devoted and eminent services rendered by him to the City and University of Aberdeen during the last forty years, as well as his powerful influence on the progress of preventive medicine and public health throughout the country. In appealing for subscriptions the committee does so in the confidence that its appeal will meet with a cordial and widespread response from all who are acquainted with Dr. Hay's high character, his acute and impartial mind, his scientific attainments and powers of organization, his fine influence as a teacher, his great place in the medical councils of the nation, and his unceasing and most generous labours in the public interest. Subscriptions (limited to two guineas) should be sent to Major H. J. Butchart, D.S.O., at Marischal College, University of Aberdeen, who is honorary secretary to the committee.

### THE HEALTH DEVELOPMENT OF EDINBURGH.

A series of lectures on the literary and social history of Edinburgh has been arranged by the Edinburgh education authority, and the third of these, entitled "The development

of Edinburgh from the health point of view," was delivered by Sir Leslie Mackenzie on February 8th. For generations, said the lecturer, Edinburgh had been badly handled, and the nineteenth century found the administrative organization hopelessly inadequate for the new problems forced upon them. It was formerly considered good civic practice that the water supply of a great and rapidly growing city should be in the hands of a private company, whose primary concern was to make dividends. In the early days the various sections of the city had to rely for water upon deep wells, but later the idea of a gravitation supply was developed. As early as 1621 the Scottish Parliament empowered the city to bring in such a supply, but for some reason it was not brought in until fifty years later. By 1840 the water supply was plentiful, but it was in the hands of the water company, and for many years the struggle went on to transfer from the company to the city the powers and duties of providing water. He looked upon the appointment in 1862 of Sir Henry Littlejohn to the office of medical officer of health as marking a new departure in civic thought. Great problems were still with them, particularly tuberculosis and venereal disease, but the city was dealing with them were active, and the situation was brought down. It was only within the last thirty-three years that the tuberculosis problem had come to be seriously tackled, and in this one Edinburgh citizen, Sir Robert Philip, had set the pace almost for the whole world. Another great health expansion had been the medical inspection and treatment of school children, which could be dated from the year 1903, when the Scottish Royal Commission on Physical Training issued its report, and recommended the medical inspection of school children. The scheme of maternity and child welfare was another great development which had sprung, under the stimulus of the war, from the voluntary system of health visiting.

### HOUSING IN SCOTLAND.

At a meeting of the Eastern District Committee of Stirling County Council on February 8th an application was made for sanction to erect twenty-four houses of three apartments, and eight houses of two apartments, with scullery, bathroom, etc. Dr. Adam, county medical officer of health, pointed out that under the Housing Act houses of three apartments were the minimum unless there were special circumstances to warrant two apartments. Mr. T. D. Wallace said that the conditions laid down by the Scottish Board of Health were hindering the building of houses. The chairman, Captain Harvey, remarked that the Board of Health was now willing to consider a certain proportion of two-roomed houses. Dr. Adam said that approximately 50 per cent. of the population of Scotland were living in two-roomed or smaller houses, a condition of affairs which should not persist. The matter was remitted to the Public Health Committee.

## Ireland.

LOCAL GOVERNMENT BILL (IRISH FREE STATE).  
THE Local Government (Temporary Provisions) Bill was read a second time at a recent meeting of Dail Eireann. In 1919 the Local Government Board, which then administered under the British Government, withdrew the usual health and other grants to the local authorities unless they undertook to carry on local administration as hitherto. The result was that nearly all the local boards and councils severed their connexion with the Local Government Board, and there was formed, to meet the new situation, a Local Government Department under Dail Eireann which discharged, in the twenty-six counties, practically all the functions of the old board, and carried out important reforms. In the Free State, with the exception of a few counties, all the boards of guardians — they averaged six for each county — were abolished; their functions under the Medical Charities and other Acts relating to health are now administered through a health board or committee, one for each county. There is no fixed number of members for a county health board, but it generally consists of about thirty. They are appointed by the county council, and most of them are members of that body. In a few counties the medical practitioners were asked to nominate representatives for the county health board, and at present there are two medical practitioners on the health boards for Clare and Wexford. That medical representatives should be appointed on the county health boards was a recommendation

made in the report of the Irish Public Health Council. The Irish Public Health Council, in making this recommendation, suggested that medical officials—for example, dispensary workhouse doctors, etc.—should be eligible for membership; the object was to bring the county health boards into closer touch with their medical officials in order that there may be better co-operation in administration.

It seems evident that Section 13 of the new bill is specially drafted to prevent county health boards having as members part-time medical officers who are employed by these boards or any other local authorities. This section can only be regarded as a very retrograde step, as it will deprive the county health authorities of expert medical advice in administrative matters which they have at all times badly needed. Nor will it help that co-operative spirit between health authorities and their medical officers which is so essential to success in Irish medical administration. Section 10 of the bill provides for the superannuation of officials whose offices are abolished as the result of the recent amalgamation of workhouses and their hospitals. This section has for its main object the radical alteration of Section 8 of the Local Government Act, 1919, which was to protect existing officers of local authorities from arbitrary removal from office, and to give to every such officer who had become incapable of discharging his duties owing to permanent infirmity, or who attained 60 years of age and had served in his office for twenty years, the right to retire on a pension. Under the eighth section of the Local Government Act, 1919, the local authority, irrespective of the number of years served by an officer, may vote him a maximal pension of two-thirds of the salary, fees, and emoluments which he was in receipt of at the time of removal or resignation, or a minimal pension of not less than an allowance, in accordance with his years of service, calculated as provided by the scale under the Superannuation Acts, 1834 to 1892. If the new bill becomes law in its present form it will only secure an official the minimal pension as calculated previous to the passing of the Local Government Act, 1919.

The Minister for Local Government, in moving the second reading, stated that its chief purpose was to regularize certain things that had been done without legal sanction during the Anglo-Irish war. If the bill became an Act it would cease to have force after March 31st, 1924. In the meantime he hoped the Government would bring forward a very comprehensive reform of the entire Poor Law system, including the Medical Charities Acts.

## Correspondence.

### STATE HOSPITALS.

SIR,—My attention has to-day been called to a letter signed by the senior medical officer of the Walton Infirmary and published in the BRITISH MEDICAL JOURNAL of February 3rd. The writer quotes some observations of mine on State hospitals abroad, and treats them as applying to Poor Law infirmaries in this country. I have never spoken of the officers and staffs of these institutions except with the greatest regard and admiration for their services to the sick and ailing, and Dr. MacWilliam is entirely mistaken in supposing that my criticism applied to them.—I am, etc.,

Richmond, Surrey, Feb. 8th.

CARE.

### HOSPITAL POLICY.

SIR,—I am glad to see that the discussion on this is being continued, for I am certain that it is one of the most important, and yet most difficult, matters that the profession has to consider. The hospital-using public recognize the great debt that they owe to the honorary staffs, and would like to make them some return; but I do not think the time is ripe for that return to be direct payment from contributory funds, especially as nearly all those funds are being collected with the understanding that the payments are solely for maintenance. The differences of opinion in the profession are very marked, some wishing to retain the present purely honorary system, some to receive a peppercorn acknowledgment (these having an eye on future developments), and some frankly wishing to receive definite payment.

There is one method that might reconcile these divergent opinions, and which would, I think, meet with the contributors' approval. Could not a definite proportion of all money paid by patients be put to a pension fund? The age

at which this might be drawn should be a fairly early one, say 55 or 60, so as to give the younger men a chance of getting on the staff without such a very long wait. Although pensioned, the retiring members could be made use of for consultant and special work. I have not yet sounded contributory members as to this, but I am pretty certain that it would meet with their approval. Hospitals, too, will be able to afford this when contributory schemes become, as I think they will, universal.—I am, etc.,

L. S. LUCKHAM,  
President, Salisbury Infirmary League.

February 12th.

SIR,—Dr. Flemming (February 10th, p. 261) allows that the policy of the Council has not even now been adequately discussed, and is not yet, in 1923, ripe for presentation to the public. I agree most heartily, and therefore cannot excuse those who in 1921, by methods which I detailed with absolute accuracy in my letter of December 16th, 1922, foisted this policy upon us at Newcastle. What plea can now be urged for men who laid upon us then a duty which only one of them has even yet dared to undertake himself, and which Dr. Flemming still to-day declines? The suggestion to tax small individual payments is not only repulsive to a large body of the profession, but never had the remotest chance of general acceptance by the laity. Therefore a compromise is necessary, and that which we suggest is reasonable, can be defended before lay boards, and was accepted by a majority at Glasgow. What more can be asked for? Whereas Dr. Flemming frankly allows that he would not attempt to approach any hospital board with his proposal, I have not only done so, but secured the approval of our board to mine, conditional upon its acceptance by the British Medical Association. When supporters of the Council can claim the like I shall begin to take them seriously, but not before.

In our hospital, which typifies many provincial county hospitals in rural areas, many contributors who can pay are able to afford but 10s. weekly or less—in fact, not enough for the "bare necessities of life." I deny absolutely the "important premiss" which he quotes. I do not for one moment allow that these small individual contributors can be considered to pay for our services by such means. I would go farther and state emphatically that to encourage in them any such notion would be a blunder in policy of the first magnitude, calculated to react most injuriously upon the status of our profession now, and yet more disastrously in the future, should hospitals be taken over by the Government or municipal bodies. As regards contributory schemes, there is a vast difference between a great insurance scheme, involving in the mass a large sum of money, carrying definite obligations undertaken by the hospital, and securing admission in priority for its beneficiaries, and a payment for services actually rendered, by a person admitted solely on his merits. Therefore my classification is quite legitimate. I would suggest that where the payment is made by the patient or his relatives, only the excess over that required for maintenance be taxed, but in all other cases the total sum actually paid for the patient, or, in the case of mass contributions, a sum agreed between the staff and the board, be the basis for assessment.

I do not think it possible to make cast-iron regulations to govern all hospitals alike, and one of the great advantages of our scheme over that of the Council is that it allows latitude of interpretation as to what constitutes maintenance, and can therefore be varied to suit local conditions. In our hospital we agreed to accept 30s. as cost of maintenance. I would ask Dr. Flemming to give this proposal more careful consideration than it has yet received, always bearing in mind that the ultimate decision lies, not with the profession as he implies, but with lay boards of hospitals, and that it is quite impossible to coerce the latter, seeing that they are unpaid, and can resign at any moment without loss to themselves if we annoy them. Has Dr. Flemming considered in detail exactly what we should do in such event? It is an interesting problem which I submit to the earnest attention of the Council and Hospitals Committee, before they embark upon a rash and ill considered adventure, which can have only one end, and that a pitiful one. I would again point out that neither Dr. Flemming nor anyone else has even hinted how, when the staff and lay board are both paid, hospitals shall be financed, yet retain one shred of that voluntary control for which the Council and Hospitals Committee profess such reverence; yet we are assured that payment of lay boards

will necessarily result from the acceptance of their policy. It follows that we must choose between rejection of this policy and rejection of the voluntary system. The answer will be given at Portsmouth. Finally, as regards "token payments," seeing that no legal question of property rights can conceivably arise, I am at a loss to understand on what grounds a proposal so fantastic can possibly be defended. Does anyone imagine we are going to approach our lay boards with a proposition so absurd?—I am, etc.,

Chichester, Feb. 10th.

G. C. GARRATT.

### THE DANGEROUS DRUGS REGULATIONS.

SIR,—In the letter from Colonel Smith in your last issue I am doubtful whether by "British Medical Councils" he means the General Medical Council or the Council of the British Medical Association. If it be the former the matter must rest until the May session of that body. If, however, he should mean the Council of the British Medical Association he will find, by reference to the reports of the Representative Meeting, of the Council acting through its appropriate (Medico-Political) Committee, and to Current Notes *passim*, as published in the BRITISH MEDICAL JOURNAL, that on the introduction of the first draft of the Dangerous Drugs Regulations the Council took very strong objection to them *in toto*, and reinforced that objection by letter and interview. The result was that certain modifications were introduced, but they were not improved sufficiently to satisfy the Association. Working in conjunction with the pharmacists, the Association requested the Home Office to appoint a Select Committee which should be competent to bring these regulations into a form which, while protecting the public, should safeguard the interest both of the medical and pharmaceutical professions. On this being refused letters were sent round to all Divisions and Branches of the British Medical Association, asking them to approach the members of Parliament for their districts and to request them to attend a meeting at the House of Commons, when the case for alteration and modification of the regulations would be put before them. As a result of this action a meeting of over 200 members of Parliament was held in one of the committee rooms of the House and the case for doctors and pharmacists most ably put before them by Dr. Cox, the Medical Secretary of the Association, and by Sir William Glyn-Jones. While this meeting was in progress a message was brought in from the Home Secretary announcing that he had decided to appoint a Select Committee as requested. As a result of the deliberations of this body the regulations were reintroduced in a very much more satisfactory form, to which no objection was taken by the Council of the Association.

When the new regulation which prohibits the doctor from prescribing certain dangerous drugs for his own use was contemplated, the Medical Secretary and I met Sir John Anderson and Sir Malcolm Delevigne at the Home Office, and vainly endeavoured to convince them that the regulation as proposed was useless and impossible to carry into effect.

At the present time the matter is receiving active attention at the hands of the Medico-Political Committee, which is collecting evidence as to the working of the regulations throughout the country. The Insurance Acts Committee has also protested against regional medical officers of the Ministry of Health being employed as inspectors under the Dangerous Drugs Regulations, and there at present the matter rests. Perhaps, on the whole, it may be better to have a medical practitioner as an inspector rather than a policeman.—I am, etc.,

E. B. TURNER,

Chairman of the Medico-Political Committee,  
British Medical Association.

February 12th.

### THE SURGERY OF THE PROSTATE.

SIR,—I have no desire to disturb the charm which "the directness and economy of means employed" in the "classical" operation of Freyer appears to exercise on Mr. Gerald Ralphs; but I feel that I ought to comment on some of his criticisms of my recent article on prostatectomy, published in your columns (February 10th, p. 259). I am surprised to learn that "many urologists" in this country use the two-stage operation as a routine procedure. I had not heard of their "increasing partiality."

To be forced into doing a routine two-stage operation because the majority of cases of enlarged prostate are "potentially uraemic" is absurd. The term is so vague as to have

no weight in deciding whether a one-stage or a two-stage operation should be performed.

Mr. Ralphs quotes the writings of Sir Peter Freyer to prove that there is never any difficulty with the abdominal wall and never any bleeding that cannot easily be controlled with hot water, or danger of sepsis from the rectal finger. I have the advantage over Mr. Ralphs of having worked alongside Sir Peter Freyer and being closely in touch with his cases during the whole period of his activity in prostatic surgery. What I have stated in regard to these disadvantages of the Freyer technique is the result of direct observation of Freyer's cases, as well as my own and those of other surgeons. My articles on the complications of this operation were published during Freyer's lifetime, and they elicited no response from one not prone to overlook such matters.

The operation that I have described is, Mr. Ralphs says, "by no means new." He saw a paper by Dr. E. S. Judd in 1916 describing it. I confess I had not seen this article, so I have looked up the Mayo Clinic reports for 1916 and subsequent years. In 1916 there are illustrations, but no description, of an open operation where the prostate is being partly dissected and partly enucleated by the finger in the Trendelenburg position. In 1917 there are similar illustrations and a short note about the control of bleeding.

Before that time I had been trying enucleation and dissection of the prostate in the Trendelenburg position with my bladder retractors in place, and had given it up in all but small fibrous or malignant prostates as being cumbersome and unsatisfactory. I then resorted, at first in a few cases and gradually as a routine method, to the operation I have described many times. In 1920, after my description of the operation was published, I saw Dr. Judd at Rochester operating in the method he had illustrated. He was using my bladder retractors very slightly modified, and told me one of his colleagues had brought them from London. The operation illustrated in Dr. Judd's article and the operation which I saw him perform is not the operation that I described.

Mr. Ralphs finds the open method difficult, and states that it is not an operation for the general surgeon. The question as to whether the operation was one for the general surgeon had not occurred to me. My object has been to get the best result for the patient, not to suit the operation to the general surgeon. But is Mr. Ralphs really qualified to speak for the general surgeon? I personally know many general surgeons who practise the operation that I have described and are satisfied with the technique.

Lastly, let me say that I hold no brief for an open operation if better results can be obtained by other methods. During the last three years I have published a series of articles dealing with the complications of suprapubic prostatectomy as I have seen them. It was to meet these complications that the open operation and other details of technique were developed, and not to push any special operation.—I am, etc.,

JOHN THOMSON-WALKER.

London, W., Feb. 12th.

### TREATMENT OF TUBERCULOSIS OF THE CERVICAL GLANDS.

SIR,—Dr. Flecker's letter in your issue of February 3rd (p. 211) on the comparative merits of treatment by operation and by irradiation raises a question that many surgeons and medical men are called upon to answer in daily practice. That the operative treatment of tuberculous adenitis still possesses a somewhat precarious reputation cannot be doubted or, indeed, wondered at. Yet the discussion on this subject, so ably introduced by Mr. John Fraser at the last meeting of the British Medical Association, showed that British surgeons of much experience in this branch are wholeheartedly in favour of operative treatment subject to certain limitations. My own experience in several hundreds of such cases leads me to submit to Dr. Flecker and to others who question the position of surgery in this disease that the localized type of disease in the upper deep cervical group in children, which is breaking down, or which resists non-operative treatment over a reasonable length of time, can be cured with certainty by a clean dissection operation, and that there is no other method available which offers the same prospect of a permanent and speedy cure in this type of case. If the surgeon is not prepared to perform such an operation then it is far better to abstain from lesser operative measures and to employ irradiation or tuberculin injections to deal with subcutaneous abscesses by repeated aspiration and injection of Calot's fluid, and not to overlook the value

of bodily rest during the active stage. The evil results of operation are due to its inadequate performance (particularly the perfunctory scraping operation without visual exposure of the seat of the disease), or to its performance in unsuitable cases; amongst the latter may be placed children under 18 months to 2 years of age, cases of widespread disease on both sides of the neck, and lastly the type resembling lymphadenoma.—I am, etc.,

Manchester, Feb. 8th.

H. H. RAYNER.

#### PENAL DISCIPLINE.

SIR,—Dr. Mary Gordon is still a little misleading to the general reader. Only experts would know that when she says that girls are "put in irons" she means that they are restrained in a canvas body-belt with handcuffs of her own design—a design for which she claims that the patient cannot injure herself or anyone else—and that such confinement is for their own protection only and subject to the authority of the medical officer, checked by the visiting committee.

The girl mentioned by Dr. Mary Gordon was, as she (I think) means to say, of superior education and surroundings, and she had had exceptionally favourable opportunities of living a normal and successful life, for she had been on the staff of a leading London bank, of the Pensions Ministry, and of the Admiralty. But everywhere she had committed thefts. She was, in fact, so unbalanced that she was unfit to live in the open, and when she was transferred from Aylesbury to Rampton she destroyed herself in a fit of jealousy because another girl had been given a position which she desired. May it not reasonably be suggested that but for the use of Dr. Mary Gordon's improved method of restraint at Aylesbury the girl would have killed or seriously injured herself at a much earlier date?

I am not in the slightest degree responsible for the conduct of Borstal institutions, but the care of inmates on their release has brought me in contact with the officers of these institutions. They are not permitted to speak for themselves in the press, and should not suffer hasty and unmerited criticism.—I am, etc.,

WENYSS GRANT-WILSON.

The Borstal Association, London, W.C., Feb. 12th.

### Obituary.

#### ALFRED EDWIN HARRIS, D.R.C.P. AND S. EDIN.,

Formerly Medical Officer of Health, Metropolitan Borough of Islington.

It is with regret that we record the death on January 24th of Dr. Alfred Edwin Harris, who in 1921 retired from the position of medical officer of health for the metropolitan borough of Islington. He was born in 1850 and received his medical education in Cork and Edinburgh; he obtained the diplomas of L.R.C.P. and S. Edin. in 1876. After engaging in general practice in Gosport for about six years he was elected the first whole-time medical officer of health for the borough of Sunderland and for the Sunderland port sanitary authority. He was also public analyst for Sunderland. In 1892 he was appointed medical officer of health to the Islington Vestry and subsequently to the metropolitan borough of Islington. Even while in practice he took a keen interest in public health, and when the Annual Meeting of the British Medical Association was held in Ryde in 1880 he contributed a paper on "The compulsory notification of infectious diseases." The problem of infant mortality engaged his attention at an early date, and suggestions which he made in 1879 for the employment of what in effect were health visitors actually materialized in later years, although in his own borough of Islington it was some time before he could persuade the borough council to give him a sufficient staff of these officers. He wrote very forcibly, and had the knack of pointing his argument by apt and well considered illustrations. Speaking at the meeting of the Sanitary Institute at Newcastle-upon-Tyne in 1882, on infant mortality, he said:

"I cannot believe that an Almighty hand ever sent these little ones into this world, that having lived in it an hour, a week, a month, a year, they should gain an eternity. Surely He never intended that these new spokes in the wheel of life should be injured or fall out through being rolled over rough and broken ground that it was never meant they should travel over."

With the coming into being of the metropolitan borough councils there was an awakening of the public health conscience in London, and Harris continued with increased vigour the efforts he had made under the vestry to improve the

conditions of life of the inhabitants. How well he succeeded is recorded in his annual reports, the bare statements which they contained of decreased sickness, fewer deaths, and lengthening of life bearing testimony to the success of his efforts. He was essentially a pioneer and was never ashamed of appearing to be ahead of his time. He was among the first to advocate the notification of phthisis and of ophthalmia neonatorum, to press for the appointment of women sanitary inspectors, and to call for a clean milk supply. On his retirement in 1921 he had the satisfaction of leaving a public health department every detail of which had been built up by his untiring efforts and indomitable pluck. The inhabitants of Islington through all time will have cause to be grateful to Alfred Edwin Harris.

#### PROFESSOR RÖNTGEN.

THE scientific world, and not least its medical members, will learn with profound regret of the death of Professor Röntgen at Munich on February 10th. Down to four years ago he was director of the Physical Institute of that city, a post to which he was called from Würzburg some years after his discovery of  $x$  rays.

Professor Conrad Röntgen was born in Rhenish Prussia in 1845. He received his early education in Holland and in Switzerland, and later studied at the University of Zurich, where he received the degree of D.Sc. in 1869. After holding the usual minor appointments at several German universities, he went to Würzburg as professor of physics, and it was there that he made his discovery of the mysterious rays, designated by him " $x$  rays"; to this day the name is used for the rays otherwise known all over the world as Röntgen rays.

The discovery was to some extent accidental, and Röntgen himself was the first to acknowledge the fact, though it must be stated that he was at the time engaged in a painstaking investigation into the action of the Crookes's tube. If proof were needed of the thorough scientific manner in which Röntgen probed into the secrets of nature, it is afforded in his subsequent action; he did not immediately publish his discovery, but from November 8th, 1895, to early in January, 1896, he devoted himself to a number of experiments ascertaining and recording physical data which have stood the test of time and are clear evidence of his great ability as a research worker. He communicated his results to the Physical Society of Würzburg in January, 1896, and the value of his discovery cannot even now, after the lapse of over twenty-five years, be estimated fully, for in spite of immense developments along special lines we are still only at the beginning of other developments which may prove to be of even greater importance. In physics theories previously current have been revolutionized; great progress has been made in the study of the structure of the atom; Laue has demonstrated the diffraction of  $x$  rays by crystals; Sir William Bragg has pointed out the similarity between  $x$  rays and light waves, and Bragg the younger has shown how the crystal reflection of  $x$  rays can be utilized to separate out the different wave-lengths. It was with the aid of the  $x$ -ray spectra that Moseley did his great work on atoms, and formulated the table of elements based on atomic numbers—work which will ever be associated with his name.

The value of  $x$  rays in medicine is hardly less great. From the very outset it was realized that a new and most powerful agent had been discovered. Röntgen was the first to observe that a fluorescent screen lying near a Crookes's tube which was covered with black paper to exclude the light from the tube when it was in action lighted up with a faint green fluorescence, and that the shadow of an object lying between the tube and the screen was plainly seen on the screen; he then used his hand as the opaque object and saw the outline of the bones. Here then was heralded, by the discoverer of the  $x$  rays himself, the birth of fluoroscopy. But Röntgen could not then have had any idea of the immense boon his discovery was to be to countless thousands of sufferers, and the immediate value of the rays to the medical profession. The developments in radiology have been very great, and elaborate methods have been evolved for the examination of practically every region of the human body. In the early days a radiogram of the hand was produced with an exposure of about twenty minutes; by the very powerful apparatus now used a much better picture can be obtained in about 1/100 of a second; that is a striking example of the advance made in one direction. In tube construction very great improvements have followed upon

## Medical News.

A JOINT meeting of the Röntgen Society and the Physical Society will be held on February 23rd, when there will be a discussion on the measurement of  $x$  rays.

At a meeting of the Medical Officers of Schools Association to be held at 11, Chandos Street, Cavendish Square, W., on Friday, February 23rd, at 5 p.m., Dr. J. G. Forbes will read a paper on "Diphtheria carriers in children of school age."

COURSES of lectures on "The diseases of the periodontal tissues due to infection in their relation to toxæmia" will be delivered in London, Edinburgh, and Manchester under the auspices of the Dental Board of the United Kingdom. Each course will consist of four lectures, and is intended primarily for registered dentists and medical practitioners. Dental students and candidates for the prescribed examination of the Dental Board are invited to attend; tickets of admission are not required. The course in London will be given at the Royal Society of Medicine (1, Wimpole Street, W.) on March 1st, 8th, 15th, and 22nd, at 5.30 p.m. The course in Edinburgh will be delivered in Professor Thomson's lecture room at the University on March 2nd, 9th, 16th, and April 7th, at 5.30 p.m. The course in Manchester will be given in the Physiology Lecture Theatre, Victoria University, on March 1st, 8th, 15th, and April 6th, at 5.30 p.m. The lecturers are Mr. J. Howard Mummery, Mr. J. G. Turner, Sir William Wilcox, and Professor E. E. Glynn, who will deal respectively with patho-histology, local clinical symptoms, systemic effects, and bacteriology.

It is proposed to add to the accommodation provided at St. Mark's Hospital for cancer, fistula, and other diseases of the rectum by erecting on vacant land adjoining the present hospital an additional building, to contain twenty-one beds, a new out-patient department, and new pathological and  $x$ -ray departments. The estimated cost is about £10,000.

A BOOK on orthopaedic surgery by Sir Robert Jones, lecturer on orthopaedic surgery in the University of Liverpool, and Dr. Robert W. Lovett, professor of orthopaedic surgery in Harvard University, is in the press. It is a large volume, will contain 729 engravings, and will be published by William Wood and Company of New York.

A DISCUSSION on partial sterilization of soil will be opened by Sir John Russell, F.R.S., and Mr. H. G. Thornton, both of the Rothamsted Experiment Station, at a meeting of the Association of Economic Biologists, to be held at 2.30 p.m. next Friday at the Imperial College of Science.

SIR CHARLES BALLANCE will deliver a short appreciation of the life and character of the late Hunter Tod, F.R.C.S. (sometime President of the Section), to the members of the Otological Section of the Royal Society of Medicine, at 1, Wimpole Street, W., to-day (Friday, February 16th), at 5 p.m. Old friends and colleagues are invited.

It is announced that the Council of St. Bartholomew's Hospital Medical College has acquired, for the purpose of extension, a block of premises in Giltspur Street, facing the main hospital buildings, and containing 17,000 sq. ft. of floor space, for new laboratories, lecture rooms, etc. We understand that these premises have been acquired from John Bell and Croyden, Ltd. (incorporating Arnold and Sons).

THE seventh annual report of the National Council for Combating Venereal Diseases, covering the period from June, 1921, to June, 1922, which has just been issued, contains a general account of the Council's activities, centrally and through the branches, which now number nearly a hundred in Great Britain. The Council's executive committee, being of opinion that information from countries, especially Canada, where legislation requires continuous treatment, would be of value, asked the Ministry of Health to authorize a commission from this country to inquire into the conditions in Canada with a view to ascertaining whether some of the steps adopted there with apparent success could not be taken in this country also; owing to existing financial circumstances the suggestion was not accepted. Inquiries were then addressed directly to the provincial health departments in Canada, asking for information of the legislation. Almost every

was to the effect that the system of in force did not prevent people working fairly well as between the sexes. The district conferences of the Council in this country have, it is stated, afforded evidence of a growing public opinion in favour of legislation enforcing continuous treatment of infective persons. Questions on this subject were circulated to the members of the Council and branches and members of other organizations represented on the Council. Most of the replies expressed the view that the health authorities should

have power, to be obtained by legislation, to compel infective persons to remain under treatment, while the confidential treatment of persons willing to continue until they were non-infective should be preserved. Views were divided as to whether public opinion, in the districts of those replying, was ripe for such a change. Alternative proposals included one for the reporting by medical officers of clinics, and by private practitioners, of cases of syphilis and gonorrhoea among infants, children, and adolescents, to the school medical officer, with a request that the school nurse should follow up those failing to attend for treatment. The work of the colonial commissions sent out by the Council is reflected in reports from the allied councils and branches overseas. At several places at which the commissions touched facilities for treatment have since been provided or extended, and at Trinidad a Venereal Diseases Ordinance has been passed which is said to be checking quack remedies. In reply to a request for a Government grant of £15,000 for 1921-22, the Council was informed that this amount must be reduced by £1,000, that a further reduction of 30 per cent. must take place in the Government grant for 1922-23, and that after the end of 1923 the Government hoped that no further financial call would be made. The Council is therefore taking measures to increase its income from voluntary sources.

SIR FREDERICK TREVES'S new book has been published this week by Messrs. Cassell (7s. 6d.). It contains twelve stories or sketches, and the title of the book—*The Elephant Man*—is that of the first, which is a moving account of the sufferings and the psychology of a young man whose terrible deformities made him a show; in certain areas immense hypertrophy of the skin was present, and there were, in addition, bony deformities of the skull and face. The case was fully reported in our columns, with illustrations, on December 11th, 1886 (p. 1183), and on April 19th, 1890 (p. 916).

A COURSE of three public lectures on psychology and psychotherapy will be given in the Department of Psychology, King's College, on February 19th, 26th, and March 5th, at 5.30 p.m., by Dr. William Brown, Wilde Reader of Mental Philosophy in the University of Oxford.

MRS. MARRYAT, sister of the late Sir James Caird, of Dundee, has presented £20,000 to Dundee Royal Infirmary. The directors were about to issue an appeal for that amount to provide additional operating theatres, a central electrical department, etc., but, thanks to this generous gift, the appeal will not now be made.

CASES of small-pox continue to be reported here and there. At Doncaster down to February 9th there had been a total of 93 cases; 8 had occurred within the preceding week. Two or three others were notified at Bentley, not far off, but at Heanor (Derbyshire), where there had been 49 cases, there were signs of abatement. In January the total number of cases in the Basford rural district were 11.

THE Yorkshire Association of the University of Edinburgh met at the Midland Hotel, Bradford, on January 24th. At the general meeting it was decided that the society be known in the future as the West Riding Association. An enjoyable dinner followed, at which sixty members and guests were present. The president, Dr. Rabagliati, proposed the toast of the University. Professor Lorrain Smith, the guest of the evening, in his reply traced recent developments and changes in the University, referring especially to its connexion with Paris and to the recent lamented loss of several of its distinguished teachers. He warmly congratulated the society on its successful resuscitation and took back the best wishes of the graduates to their Alma Mater.

PROFESSOR VINCENT has been elected a member of the Académie des Sciences in place of the late Professor Laveran.

THE late Miss M. L. Jeffcock, of Worksop, Notts, has bequeathed £1,000 to the Sheffield Royal Infirmary; £500 to the Jessop Hospital for Women, Sheffield; and £500 to her medical attendant, Dr. George Kemp.

THE Cambridge University Press announces for early publication *Problems in Dynamic Psychology: A Critique of Psychoanalysis and Suggested Formulations*, by John T. MacCurdy, M.D., Lecturer on Medical Psychology, Cornell University Medical College, New York.

PROFESSOR BORDET of Brussels, director of the Pasteur Institute of Brabant, has been made a Commander of the Legion of Honour.

THE Ministry of Health has issued draft regulations, to come into force on August 1st, with regard to the labelling and composition of condensed milk. Every tin must bear a label specifying whether it is full cream, unsweetened, or as the case may be, and stating the equivalent volume of milk (or skimmed milk) contained in it. Tins of condensed skimmed milk are to be labelled "unsuitable for babies," and instructions as to dilution must be quantitatively accurate. The regulations provide further that condensed milk sold as "full cream unsweetened," or "full cream sweetened," must contain 9 per cent. of milk fat.

THE Council of Epsom College will shortly award "Franco" pensions of £30 a year to medical men. Candidates must not be less than 55 years of age, and their yearly income, independent of any allowance from the College, must not exceed £100. Application should be made to the Secretary, Mr. J. Bernard Lamb, 49, Bedford Square, W.C.1.

A CIRCULAR (366) has been issued by the chief medical officer of the Ministry of Health, stating that it has been decided to discontinue the practice of forwarding special forms of inquiry when cases of encephalitis lethargica are reported. The facts obtained by these forms have recently been summarized in a report (noticed in the JOURNAL of October 7th, 1922, p. 654), and it is considered improbable that the collection of further details by means of these forms will provide much additional information. It is pointed out that encephalitis lethargica remains on the list of diseases which are compulsorily notifiable, and that the Ministry of Health undertakes the examination of cerebro-spinal fluid in cases of suspected cerebro-spinal fever. The work of Dr. E. G. D. Murray for the Medical Research Council on the subject of the production of an immune serum for therapeutic use in cerebro-spinal fever has been retarded, it is stated, by scarcity of material, and pathologists are asked to send cultures of freshly isolated strains of meningococci from the cerebro-spinal fluid of cases of meningitis direct to Dr. Murray, at the Field Laboratories, Milton Road, Cambridge; special outfits for this purpose may be obtained free of cost at the offices of the Medical Research Council, 15, York Buildings, Adelphi, London, W.C.2.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

The postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic address is:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Attilio*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Medisecra*, Westrand, London; telephone, 2632, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Biocillus, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

## QUERIES AND ANSWERS.

DR. MAUDE K. HOSAIN (110, King's Gate, Aberdeen) writes: If any of your readers could spare their quarterly copy of *Brain* after they have finished with it, to send to one of the German universities, will they kindly communicate with me?

### DISTEMPER IN DOGS.

DR. J. S. MANSON (Warrington) writes with reference to the proposal for research into the etiology of distemper (BRITISH MEDICAL JOURNAL, February 10th, p. 249): I have been under the impression for some years that the bacillary origin of distemper was discovered by McGowan of Edinburgh, and that this discovery had been corroborated by American workers. Reference is made to McGowan's researches into canine distemper and other diseases of domestic animals in the book entitled *Edinburgh's Place in Scientific Progress*, issued to the members of the British Association attending the annual meeting in 1921. The great interest shown at the Glasgow meeting of the British Medical Association in the papers and discussion on animal and plant pathology, to which Sir Clifford Allbutt made a notable contribution, induces me to express the hope that someone familiar with these topics will say whether we are as ignorant of the cause of canine distemper as is implied in the statements of the lay press.

Dr. McGowan has done a great deal of work with regard to distemper, and has described an organism, *B. bronchi-septicus*, the only cultivable micro-organism which he found to be present with uniformity and in great numbers in the tissues and organs of cases of canine distemper. He has stated also that typical distemper may be induced by infection with pure cultures of this micro-organism, and that dogs which have recovered from attacks so induced are protected on exposure to natural distemper. Dr. McGowan's experiments have led him also to the conclusion that distemper occurs in many other animals besides dogs, and he has described an outbreak, among pigs, of a destructive infect on which he believed to be distemper. We gather, however, that Dr. McGowan's results have not so far

been generally accepted by the veterinary profession, and we must assume that the Medical Research Council is of opinion that further inquiry is needed. We hope to recur to the subject on a subsequent occasion.

## LETTERS, NOTES, ETC.

### RITTER'S DISEASE.

DR. D. WALSH (London) writes: The rare condition described by Dr. Ronald Cairns in your issue of February 3rd (p. 188) suggests an origin in local anaphylaxis. A similar explanation possibly or probably applies to those rare cases in which bullae persistently follow slight traumatism. The precise nature of the antigen in either instance would still have to be ascertained, and naturally one would investigate food idiosyncrasies, at any rate in elder children or adults.

### EARLY HUMAN OVA.

DR. R. H. BOTHAM (Skelton-in-Cleveland) writes: Some time ago an embryologist was inquiring through the BRITISH MEDICAL JOURNAL for early fertilized ova. I have a good specimen of seven weeks, which I shall be pleased to send anyone interested. Also a foetus of ten weeks.

### A MISQUOTATION.

DR. C. F. CLARKE (Woolwich) has put his finger on a misquotation in our issue of February 3rd. He says: "The writer of the obituary notice of Dr. Dickson of Marlow introduced a verse from Tennyson at the end. But

"The peaceful stream glides on  
Through the vale and under the hill"

should be

"And the stately ships go on  
To their haven under the hill."

The lines are from "Break, break, break"—a tiny classic—which will not bear a word of alteration.

We submitted this to the author of the memoir—"J. A. P. P."—who pleads guilty, and asks to be allowed to set himself right with our readers.

"I was rash and presumptuous," he says, "in daring to alter the beautiful words of the great Victorian poet to suit the changed locale from Severn Sea to Father Thames; in a footnote in the obituary notice I ought perhaps to have apologized for so doing, but such a note appeared to me inappropriate. I am therefore all the more grateful to you for giving me this opportunity of explaining and apologizing to your readers."

This handsome admission impels us to add a word of apology on our own account for the lapse from editorial vigilance.

### DETERMINATION OF SEX.

DR. REGINALD MAPLES (Kingsclere) writes: Dr. R. A. Parker's letter (January 27th, p. 174) is most interesting to me, but exactly opposite to my own experience. For the past thirty-five years I, together with many friends, have systematically bred from our small herds calves of the sex we wished by simply following the following rule: If a cow has a bull calf and you wish to continue bull calves you must send her to stock on the second, fourth, or sixth period of coming "on use." If, on the contrary, you desire heifer calves you must send her on the first, third, or fifth period, and so on, till she is stopped. This rule is infallible if you have a reliable cowman to keep observation. This does not apply to a heifer with her first calf, because you have no record how many times already she has been "on use." I have helped many a farmer to breed to sex by giving him this advice. I have some extraordinary reliable records.

### ERRATUM.

IN Dr. Mary Gordon's letter on penal discipline (BRITISH MEDICAL JOURNAL, February 3rd, p. 212) the sixth line of paragraph 5 should read "superior surroundings and education," etc., not, as printed, "inferior."

### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 30, 31, 34, and 35 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 32 and 33.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 55.

## SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	0 9 0
Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Half single column	...	...	3 15 0
Half page	...	...	10 0 0
Whole page	...	...	20 0 0

An average line contains six words. All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded. Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive postage letters addressed either in initials or numbers.

## An Address

ON

## ACHES AND PAINS OF RENAL ORIGIN.\*

BY

ANDREW FULLERTON, C.B., C.M.G., F.R.C.S., F.A.C.S.,  
SURGEON TO THE ROYAL VICTORIA HOSPITAL, BELFAST.

EVERY practitioner is confronted from time to time with the problem of aches and pains which raise a suspicion of some disorder of the kidney, and my intention in this address is to record my own difficulties in diagnosis, and the methods adopted to surmount them. I have gone carefully through the records of upwards of 1,500 successive cases of cystoscopy, of which I have notes, and picked out those in which pain was complained of, with a view to ascertain whether the condition of the kidney or ureter or the site of the lesion could be correlated with pain of a particular type or distribution. The results of these observations show, on the one hand, that the most extensive disease of the kidney may exist without any pain whatever, and, on the other, that a very slight departure from the normal may be associated with almost unbearable agony; also that a precisely similar condition may, in one patient, give rise to the merest local discomfort, and in another to pain of a severe character, radiating to the utmost terminations of the peripheral nerves. I have in my mind at the moment a man who used to bring in a small bottle a number of small calculi passed with the minimum of discomfort. Any one of these small calculi would be capable in another patient of producing the most intense renal colic.

Papin and Ambard in a recent article<sup>1</sup> give some interesting facts bearing on renal pain and its treatment, which will be referred to later. It will be convenient at this stage to review briefly the nerve supply of the kidney and its pelvis, based on Papin and Ambard's account.

The kidney receives its chief nerve supply through the renal plexus which accompanies the great vessels into the hilum. Branches also accompany the vessels to the capsule and accessory vessels, when the latter exist. The renal plexus comes off from the solar plexus, which is composed of a network of nerves and ganglia lying between the terminations of the great splanchnics of either side. The great splanchnic is formed by branches coming from the sixth to the tenth thoracic ganglia, receiving filaments (according to Beck) from all the thoracic ganglia above the sixth. It terminates in the semilunar ganglion, which also receives the pneumogastric and filaments from the phrenic.

The small splanchnic, which is sometimes double, is formed by filaments from the tenth, eleventh, and twelfth ganglia, and terminates either in the semilunar ganglion or passes directly into the renal plexus. The renal plexus is formed from branches issuing from the semilunar ganglia, the small splanchnics, and sometimes from the great splanchnics; it also receives a branch from the first lumbar ganglion. The plexus is composed of filaments and ganglia. The filaments follow the course of the vessels, around which they form a close network. In the kidney itself the nerves follow the blood vessels as far as their most remote terminations, and have been traced to the vascular tuft of the glomerulus. Other branches are distributed to the uriniferous tubules. Sensitive end organs have also been described in the muscular walls of the pelvis and calices, in the tunica adventitia and tunica media of the vessels, and in the capsule of the kidney. The nerves to the kidney itself are, with few exceptions, non-medullated, while those distributed to the pelvis and calices are for the most part medullated. The cells met with in the ganglia of the renal plexus are of the sympathetic type. It appears probable that renal pain proceeds from the sympathetic. According to Wundt the cells of the sympathetic oppose an obstacle to impressions, only overcome when these are of a violent nature. It is held by many authorities that painful sensations in the sympathetic system are really only perceived on quitting that system and gaining, by way of the rami communicantes, the posterior roots of the cord, and through these the cerebro-spinal centres. The result of this is that pain is often reflected along the course of nerves con-

nected with the corresponding rami communicantes. Section of the spinal cord between the eighth and ninth dorsal segments abolishes the sensibility of the kidney and ureter. Section of both splanchnics does not abolish the sensibility of either kidney or ureter. The pneumogastric takes no part in the conduction of renal pain.

We are now in a position to refer to the question of how far the kidney, pelvis, and ureter are sensitive to various stimuli.

Pressure on the normal kidney produces pain of a sickening character somewhat similar to, but much less severe than, that produced by pressure on the testis or ovary. When an operation is performed on the kidney under local anaesthesia manipulation of the organ produces pain.

The sensitiveness of the kidney to heat and cold has not been fully investigated, but would appear to be slight.

Puncture and section of the kidney are apparently not specially painful. Manipulations, however, carried out on the pedicle, and, especially, stripping back of the peritoneum, are attended with pain.

Compared with the kidney the pelvis and ureter are highly sensitive. The patient is often cognizant of the presence of the ureteral catheter in the pelvis of the kidney, and if the former is pushed too far pain may be produced. Hot and cold fluids introduced through the ureteral catheter are not clearly perceived as such. Distension of the pelvis, however, is very definitely painful. If more than 3 to 7 c.cm. of fluid are injected into a normal pelvis, pain resembling renal colic is, as a rule, provoked, and may at once be relieved by draining off the fluid injected. Pyelic pain may be very accurately studied by pyelography, or by simply measuring the capacity of the pelvis by the injection of fluid. The pain produced by distension of the pelvis commences in the subcostal region in the anterior axillary line. Tender points can be demonstrated by touch in the costo-lumbar, subcostal, para-umbilical, and iliac regions. These areas are those to which pain is referred by the cerebro-spinal nerves from impressions received by the sympathetic. Pain may be referred along the course of the nerves of the lumbar plexus towards the thigh, the testicle, or the labia majora, or it may be referred to the epigastrium or the renal region of the opposite side. Zones of cutaneous hyperaesthesia may be demonstrated by stroking or pinching the skin. The tenth, eleventh, and twelfth dorsal segments correspond in part to the kidney; the eleventh and twelfth dorsal and first lumbar correspond to the pelvis and ureter. Certain reflex phenomena such as nausea, vomiting, and pallor, with cold sweats, unassociated with disturbance of pulse or respiration, commonly accompany pyelic pain.

In pathological conditions the sensitiveness of the kidney and ureter may be profoundly altered. Papin and Ambard<sup>1</sup> classify renal and pyelic pain as follows:

1. That due to mechanical or traumatic causes.
2. That due to inflammatory conditions.

The mechanical causes are:

- A. Distension of the ureter, pelvis, and calices.
- B. Distension of the parenchyma in the capsule by congestion or oedema of the kidney.
- C. Contact of a foreign body with the walls of the pelvis or calices.
- D. Dragging of the pedicle of the kidney.
- E. Compression of nerves. Most of the pain is, however, reflex or of a toxic nature.
- F. Sclerosis of the kidney.

The inflammatory causes are:

- A. Lesions of the pelvis and calices, such as pronephrosis.
- B. Lesions of the parenchyma, such as pyelonephritis.
- C. Lesions of the perirenal cellular tissue, such as perinephritis and perinephritic abscess.

These authors are of opinion that renal pain is usually, as a matter of fact, pyelic. In calculus, hydronephrosis, movable kidney, renal tuberculosis, cancer, and renal haematuria, obstruction of the ureter declares itself by renal colic due to distension of the pelvis. Pain in the kidney itself is generally of moderate intensity except in inflammatory lesions, when it may become very severe.

It is very instructive, when one is constantly seeing cases of urinary disease, to record in the patient's own words his description of the pain he suffers. A collection of such accounts is of great interest, especially if the case is followed to its termination by operation or in the *post-mortem* room. A study on these lines shows that the most varied pathological conditions may give rise to almost identical symptoms. This supports the suggestion that a common cause may be present in

\* Presidential Address delivered before the Ulster Branch of the British Medical Association on November 30th, 1922.

all—namely, distension of the renal pelvis from some obstruction. This obstruction may be a calculus, a kink, a thickened ureter, or a blood clot. Except when obstruction is present, there does not appear to be any positive pressure in the pelvis. A proof of this is that when for any reason an incision is made into the pelvis of the kidney—say, for the removal of a stone—close, accurate, watertight suturing is not absolutely necessary to prevent leakage. The urine seems to trickle down the walls of the pelvis, as rain down the roof of a house, and if no obstruction is present finds its way into the upper part of the ureter, where peristalsis begins and forces it towards the bladder. If the obstruction has not been relieved leakage will take place. It is reasonable to suppose that the peristaltic movements of the ureter, if excessive, may be painful, just as those of the bile ducts and intestinal tube may be. Efforts by the ureter to pass on a calculus or to overcome an obstruction are probably attended with pain, but an investigation of cases with the most intense renal colic, radiating even to the toes, shows that the obstruction is quite frequently at the uretero-pelvic junction, hardly, if at all, involving the ureter. It is, of course, possible that spasm, started in the pelvis, may be transmitted along the ureter, and one does observe movements at the ureteral orifice in certain cases in which there is no efflux.

Renal pain or pyelic pain may be so slight as to pass almost unnoticed, or it may be of the most violent character. It may remain in one spot, or it may radiate widely. It may start suddenly or gradually, and may terminate in the same way. It may only last for a few seconds, or it may continue for hours. It may occur in attacks, with intervals of complete or comparative freedom, or it may be more or less constant. It may come on during exercise, or when the patient is resting quietly in bed. It is variously described as a sense of discomfort, an ache, a gnawing or burning sensation, a bursting feeling or a feeling of fullness, a stab, a tearing or cutting sensation. The intensity of the pain is no index whatever of the severity of the lesion. A minute calculus may produce the most severe agony, whilst one the size of a chestnut may give very little indication of its presence. A very slight kink of the ureter may produce more pain than an extensive hydronephrosis.

The direction of the radiation of the pain is, as a rule, towards the lower extremity, generally to the groin, the testis, or labia majora, sometimes into the upper part of the thigh, more rarely to the knee and the leg, even as far as the toes. Occasionally, however, radiation takes place towards the upper extremity, to the shoulder, arm, and fingers. Not infrequently the pain radiates to the opposite renal region, and occasionally is felt solely on the presumably healthy side. Reference has already been made to reflex nausea, vomiting, pallor, and cold sweats. A special variety of pain is that seen in some cases of movable kidney, and called Dietl's crises. The pain in these cases may be due to torsion of the pedicle, kinking of the ureter, or dragging upon the pylorus, gall bladder, or other abdominal structure. It may be suggestive of an acute abdomen with rigidity, or may be of the type already referred to in discussing distension of the renal pelvis.

A typical attack of renal colic is so characteristic that a diagnosis of something pathological in the kidney or ureter is justified, and yet the surgeon will occasionally encounter cases in which every examination that can be made fails to establish a diagnosis, and one is driven to inquire whether extrarenal conditions may not in exceptional cases give rise to colic that is with difficulty distinguished from that due to renal causes. It is important to ascertain if the site of the pain or areas of hyperaesthesia—lumbar, subcostal, para-umbilical, iliac, etc.—give any clue to the position of the causative factor. My own observations lead me to the conclusion that it is unsafe to predict from these symptoms alone the situation of the lesion. In back pressure from an enlarged prostate, for instance, pain is often complained of in the lumbar region. Pain in the iliac region may indicate the presence of a stone in the lower ureter, but is quite often present with a stone in the pelvis of the kidney. When the lesion is near the vesical end of the ureter (for example, a calculus) frequency of micturition is often complained of, but this symptom may be entirely absent in these circumstances and be present when a calculus is lodged in the renal pelvis. Pain of renal origin must be looked upon in many cases as referred pain, and its distribution as not necessarily giving any clue to the location of the lesion in the urinary tract.

#### Methods of Investigation.

Abdominal examination may discover displacements, deformities, or enlargements of the kidney, swellings in the renal region, tenderness, rigidity, or areas of hyperaesthesia. Rectal and vaginal examination may detect a calculus in the lower end of the ureter, thickening of the latter, undue tenderness, or other abnormality. Examination of the spermatic cord may disclose the presence of a varicocele suggesting renal tumour if on the right side. The urine will, of course, be carefully investigated by chemical, microscopic, and bacteriological tests. The absence of any demonstrable departure from the normal, however, does not, by any means, exclude the kidney. A small aseptic stone may be present without giving rise to any abnormal constituent such as blood, pus, or albumin. In certain cases of hydronephrosis the urine may be normal to the usual tests, and in pyonephrosis the affected ureter may be blocked at the time of examination. A tumour of the kidney may be present without showing any abnormality of the urine. X-ray examination, if thorough and efficient, will demonstrate alterations in the position, shape, and size of the kidney, besides showing the presence of opacities. Cystoscopy may demonstrate alterations in the shape, size, and surroundings of the ureteral orifice, and changes in the rate, rhythm, and character of the efflux. Ureteral catheterization will show the character of the urine from each side and any alteration of the relative specific gravities. The latter test, which I will call the specific gravity test, has been of great service to me for diagnostic purposes. Shortly stated, I find that with unilateral disorders of the kidney the specific gravity on the affected side is diminished in a large proportion of cases. If there is a difference in specific gravity on the two sides, even if no other sign is present, the chances are that the kidney which secretes the urine of lower specific gravity is pathological. A low specific gravity does not necessarily mean a seriously damaged kidney. It may be due to reflex diuresis from a small fragment of stone or from early disease. On removal of the cause (if removable) the specific gravity returns rapidly to normal.

Combined with ureteral catheterization, the subcutaneous, intramuscular, or intravenous injection of dyes, such as indigo-carmin, or phenolsulphonephthalein, may give valuable information. The time of the appearance of these dyes in the urine, the amount present in the specimens collected by ureteral catheter, and the time taken for their elimination will assist in clearing up many doubtful cases. The ureteral catheter will further demonstrate patency or narrowing of the ureter, and, by injection of fluid, the capacity of the renal pelvis. By the opaque catheter or bougie opacities discovered by radiography may be accurately located, and, if stereoscopic radiograms are employed, their position relative to the ureter and kidney accurately defined.

Finally, by pyelography the shape and size of the pelvis and calices, the presence and relations of foreign bodies, and the position, direction, and calibre of the ureter may be demonstrated with the greatest accuracy. I now use almost exclusively sodium bromide solution for this purpose. This is run in through the ureteral catheter into the pelvis of the kidney until the patient complains of slight discomfort. A radiogram is then taken, which shows with great accuracy the shadow of the pelvis and ureter.

Should these methods fail to establish a diagnosis, or for any reason be unavailable, and the surgeon be in doubt between a renal and an abdominal lesion, it may be necessary to explore. For this purpose I have in a few cases employed an oblique abdominal incision extending from the mid-axillary line just below the costal margin to the iliac region parallel to the fibres of the external oblique. The anterior part of the incision opens the peritoneal cavity, and the posterior part allows of the retroperitoneal exploration of the kidney and ureter. In this way the appendix, caecum, colon, liver, gall bladder, spleen, stomach, duodenum, tubes, ovaries and uterus, as well as the kidney, may be explored with relatively little trauma to the abdominal wall.

The possibility of disease of the spinal column or cord should always be borne in mind. Spinal caries, aneurysm of the aorta involving the vertebrae, tumours involving the spinal column or cord, and locomotor ataxy may give rise to pain closely simulating renal colic.

It now remains to mention some types of renal disorder commonly met with in practice which are attended with pain. Pain due to accompanying bladder conditions will not be discussed.

*Renal Calculus.*

Undoubtedly the most frequent cause of renal pain and renal colic in its worst form is renal calculus. Looking over the notes of 72 consecutive cases I find that pain was present at some time or another in all but two. The pain was of the most varied character. In one it was very indefinite on the affected side, and also was present on the sound side. A large phosphatic stone weighing 1½ oz. was removed from the pelvis of the right kidney. In another the pain was so slight that the patient, a young woman, was treated for fifteen years for Bright's disease. This was "cured" by the removal of a calcium oxalate stone from the pelvis of a movable right kidney. On the other hand, a patient with a small phosphatic stone the size of a pea, lodged in the pelvis of the left kidney, complained of "frightful" pain radiating to the groin and knee, associated with vomiting and rigors. The patient actually "yelled" with the pain in the knee.

The radiation of the pain in these calculus cases varied greatly. Most usually it radiated towards the groin, testis, or labia majora, frequently over the buttock, or down the inner or outer side of the thigh, sometimes into the penis, sometimes down the leg as far as the heel or toes, and occasionally all over the abdomen. In one case it started in the left renal region, radiated right up the back to the shoulder and back of the head. The patient was relieved by the passage of a small stone. A patient in whom a small stone about the size of a melon seed was removed from the right ureter near the bladder behaved like a madman during attacks of pain which, starting in the kidney, radiated to the testis. Another patient complained of cramp-like pain in the lower abdomen, and passed some small, irregular calculi about the size of split peas. Another felt "something snap in the kidney." A calculus was subsequently removed from the renal pelvis on the affected side. In a patient with calculi in both kidneys the pain was now on one side and now on the other, and radiated on both sides into the leg. The following rather rare case is worth recording:

The patient, a woman, suffered severe renal colic from the passage of a gummy material containing the characteristic spherules of calcium carbonate. The pain first affected the left side and radiated into the leg. There was rigidity and tenderness in the left loin. The urine contained a copious deposit of white material, thought to be pus, but which proved on microscopical examination to be an almost pure deposit of calcium carbonate. X-ray examination was negative. A few days later the patient had severe pain in the opposite kidney, again with the discharge of calcium carbonate. Reduction of the calcium content in the diet effected a speedy cure.

Similarly one sees occasionally cases of renal pain due to the passage of crystals of calcium oxalate, and probably other insoluble salts in the urine may cause pain. In many of these cases of renal calculus frequency of micturition, especially during the attacks of pain, was complained of. This was apart from any associated cystitis or other bladder affection. Reflex vomiting, pallor, and cold sweats were exceedingly common in the severe attacks.

*Tuberculous Kidney.*

It must be emphasized that renal pain is not a cardinal symptom of tuberculous kidney. Looking over the notes of 117 consecutive cases I find that pain was complained of in 56 cases only—that is, in less than half the number. Even in advanced cases pain may be entirely absent. In most of the painless cases there was thickening of the ureter, and, in many, very extensive destruction of the kidney substance. In one case, though the pelvis was enormously dilated and the ureter resembled a piece of small intestine, pain was not complained of. Even with a large perirenal abscess pain may be absent. In the painful cases the symptoms resembled those occurring in renal calculus, but were rarely so severe. It was described as an ache, or a soreness more or less constantly present, or a feeling of fullness on the affected side. Attacks of renal colic were, however, not uncommonly met with, but these rarely attained the intensity of those due to calculus. A few patients stated that the pain started in the bladder and radiated up into the kidney on the affected side. Some complained of "soreness" in both kidneys, and in a few the pain was on the side opposite to the seat of disease. Radiation of the pain was somewhat similar to that found in calculus. In one case the pain radiated to the shoulder on the affected side. Vomiting and pallor, with sweats, were less frequent than in the case of stone.

The pain in tuberculous kidney is probably due to intrapelvic pressure, but the chronicity of the disease allows of

more gradual distension than in the case of stone. At times, however, the passage of thick pus or debris down the ureter may suddenly increase the pressure in the pelvis and give rise to colic. The thickened, rigid ureter, so frequently present, is hardly capable of spasm.

*Pyelitis.*

Pain is a very frequent symptom in pyelitis. Thus out of 75 cases which I have noted pain was present in 59, or almost 80 per cent. In the acute cases with rigors and fever, vomiting, pain, and tenderness, with, perhaps, palpable swelling of the affected organ, and muscular rigidity were commonly present. The pain was more fixed and constant than in calculus and tubercle, and was not generally so severe as in calculus. Even in acute cases, however, pain may be entirely absent. In chronic cases pain is often absent, and the affected kidney is only discovered by cystoscopy or ureteral catheterization. In one case in which inspissated pus was squeezed out from the ureter, no pain was complained of. In a few cases renal colic was present, the pain radiating to the groin, testis, or even to the leg or foot, but the type was generally much less severe than that seen in calculus. The following case, in which the kidney was explored, is a good example of acute unilateral pyelitis.

A married woman, aged 32, had repeated rigors, with fever, sweating, rigidity, and acute pain in the right lumbar region. The right kidney was tender and painful. *Bacillus coli communis* was found in the urine. On exploration the kidney was congested and enlarged and the pelvis was dilated.

The local pain and tenderness in these cases are probably due to swelling of the parenchyma of the kidney and distension of its capsule. When colic is present it is no doubt due to the passage of purulent coagula along the ureter.

*Hydronephrosis and Pyonephrosis.*

In hydronephrosis and pyonephrosis we have the conditions most favourable to the development of renal colic—namely, obstruction and distension of the renal pelvis. As might be expected, therefore, pain is a frequent symptom in these affections. Out of 37 cases examined, pain was present in 31, and doubtful in 2. The pain, like that due to calculus and tuberculosis, varied very much in character and distribution. A very frequent history was that of pain and a tumour in the side, associated perhaps with vomiting. It is noteworthy that the radiation of the pain resembled very closely that seen in renal calculus. Now, in a large proportion of the cases the block was present at the uretero-pelvic junction, and did not involve the ureter itself, yet the pain was very similar to that said to be due to the passage of a calculus along the ureter, and attributed to spasm of the latter. Some of the cases of hydronephrosis were associated with an abnormal renal artery running to the lower pole and crossing the ureter. Hurry Fenwick attributed the pain in these cases to spasm produced by the artery acting as a bowstring to the ureter. This spasm might itself cause pain or, by narrowing the ureter, produce intrapelvic pressure, which, as we have tried to show, is the main cause of renal colic. A curious circumstance is that in some of these cases of hydronephrosis the pain is of recent onset, though the state of the kidney found at operation justifies the assumption that the condition has been present for years. The patient may have been perfectly free from pain from his youth, until suddenly he is seized with violent colic. Operation reveals a kidney reduced to a shell. Why, then, has pain not been present before? An explanation that suggests itself is that while very gradual distension spread over perhaps a number of years may be painless, a time comes when the uretero-pelvic junction becomes sufficiently kinked from the disturbed relations of the parts, caused by dilatation of the pelvis, to cause a more or less complete block. Pain is then felt, and is only relieved by the release of fluid from the dilated pelvis. In some cases hydronephrosis or pyonephrosis is accidentally discovered by palpation of the abdomen, and in others, again, there is a history of attacks of pain extending over twenty years or more.

The pain in certain cases of hydronephrosis and pyonephrosis may rival in severity that found in renal calculus, as in the following:

A man, previously healthy, began, at the age of 23, to suffer from paroxysms of renal colic. Before admission to hospital he had had three attacks at five months' intervals. The pain started in the left lumbar region and radiated towards the iliac fossa. During the attacks the patient became weak and vomited. The

urine was clear, amber, acid, specific gravity 1020, free from albumin, blood, pus, and micro-organisms. There was some tenderness in the left lumbar region but the kidney could not be palpated. X-ray examination was negative. Here was a patient with typical attacks of severe renal colic with no definite physical signs, and with normal urine—a state of affairs occasionally seen and practically always attributed to stone. Cystoscopic examination showed no change in the bladder or ureteral orifices. Catheters were introduced into each ureter, but no flow could be obtained on the affected side until the catheter had been passed as far as the renal pelvis. Then a large quantity of fluid was obtained. The specific gravity of this specimen was 1005, as against 1025 on the sound side. Sodium bromide solution, a large quantity of which was accommodated without pain, was run into the renal pelvis on the affected side. Radiography demonstrated great dilatation of pelvis and calices, and operation revealed a large hydronephrosis.

#### Renal Tumours.

Pain may be entirely absent in cases of renal tumour. It was present in 11 out of 18 cases recently examined—that is, in about 60 per cent. It was described as a soreness, a dragging pain, pain and tenderness, or severe renal colic. In one case the patient had what was described as "terrible" pain radiating down the leg and accompanied by vomiting and the passage of clots. In another case in which there was no visible blood in the urine, the patient complained of pain radiating to the outer side of the ankle. The tumour proved to be a malignant adenoma.

There are various factors which may contribute to the production of symptoms in renal tumours. The tumour may drag on, or involve, adjacent structures; by distension of the renal capsule it may cause pain; the pelvis may be partially or wholly filled with growth; the veins may be blocked with it; blood clot may be present and give rise to acute renal colic during its passage down the ureter, or detached portions of growth may act in the same way. Most of my cases who had pain suffered from renal colic of various degrees of intensity, and in most of them the cause appeared to be blood clot in the pelvis or ureter.

#### Haematuria.

In some cases of haematuria the blood is poured out in such small quantity that time is allowed for intimate admixture with the urine, and pain may be absent. In others the bleeding is so profuse that clotting does not take place until the blood reaches the bladder. In others, again, clotting takes place in the pelvis or ureter, and produces the well known symptoms of renal colic. After the passage of the ureteral catheter, when blood is drawn, it is not uncommon for acute pain to occur. No doubt in such cases the mucous membrane of the ureter is rendered more irritable by the trauma inflicted. Sometimes this pain closely simulates that produced by renal calculus. The amount of blood drawn does not seem sufficient of itself to account for it. That idiosyncrasy plays a part is shown by the fact that in some patients the smallest clot may produce very severe symptoms, while in others no discomfort is felt. This holds good in all forms of renal disorder in which pain is a common symptom.

#### Movable Kidney.

Pain is often present in cases of movable kidney, but this condition is so commonly associated with other manifestations of visceroptosis that it is difficult sometimes to apportion the blame between the various organs concerned. On the right side especially it may be impossible to differentiate symptoms of appendicitis, mobile caecum, and other abdominal affections from those due to displacements of the kidney, and mistakes in diagnosis are often made. In such cases I have found pyelography and pyelography useful. Most usually, if any difference is seen in the specimens from the two sides it is a diminished specific gravity on the affected side—due, no doubt, to a reflex unilateral diuresis. Rarely, the specific gravity is raised on the affected side—due, perhaps, to delay and increased absorption of fluid from slight kinking of the ureter. Pyelography may show some alteration in the pelvis or change in the calibre or direction of the ureter. The following case is a good illustration.

A man, aged 27, previously healthy, had a sudden severe pain in the left lumbar region, radiating to the groin and testicle. He also felt sick and vomited, and complained of a constant desire to micturate, passing only a few drops at a time. He had several similar attacks. The urine was free from albumin and pus, but contained a few red blood cells. The specific gravity of the

specimen on the affected side was 1005, as against 1015 on the sound side. Pyelography showed a sigmoid bend on the ureter just below the renal pelvis on the affected side. No calculus was seen, but the kidney was tilted and lower in position than normal. Nephropexy straightened out the ureter, fixed the kidney in its normal position, and cured the patient.

#### Other Causes of Renal Pain.

One must always bear in mind that renal pain may be due to some condition of bladder or urethra. Carcinoma of the bladder, a papilloma at a ureteral orifice, an enlarged prostate, or stricture of the urethra may cause renal pain on one or both sides from back pressure. Besides these there are some rarer conditions occasionally met with which are accompanied with renal or pyelic pain. Such are certain forms of chronic nephritis, infarcts, hydatid cyst in which small cysts are sometimes passed, giving rise to attacks of renal colic, other cysts of the kidney, and horseshoe kidney.

As a confession of failure, due no doubt to faulty methods in the past, I am bound to admit that I have only too frequently seen cases of renal colic in which I have been unable to trace the cause. In some of these the urine has been perfectly normal and x-ray examination negative. In a certain number the only indication of a renal origin has been a diminished specific gravity on the affected side. This may have been due to a small undetected calculus, a narrowing or kinking of the ureter, an accessory renal artery, or some other obscure condition which reflexly alters the blood supply of the organ. In other cases every method of diagnosis has been tried, with the sole result of excluding gross lesions. Recent advances in our methods of examination will reduce the number of undiagnosed cases and add to the satisfaction of all concerned in the investigation and treatment of these elusive complaints.

#### TREATMENT.

Cases of renal pain will be dealt with, of course, by removal of the cause, when this is possible. Papin and Ambard<sup>1</sup> point out, however, that in certain cases of painful nephritis, small hydronephroses, and renal neuralgias of ill defined character the only treatment which, up to the present, has been applied has been either insufficient or excessive. While decapsulation, temporary nephrotomy, and nephropexy are insufficient to effect a cure in a large proportion of cases of this sort, removal of the kidney is too drastic a step. In these circumstances they have devised an operation which relieves the pain and yet conserves the kidney. This consists in resection of the nerves of the kidney. The pedicle is carefully exposed, the nerve filaments accompanying the vessels are defined, seized one by one with dissecting forceps, and torn across by slipping under each a probe-pointed director. The authors state that it is not difficult to distinguish the resistant nerves from the softer lymphatics. Before the operation can be considered complete the vessels should have been stripped of all the nerve filaments surrounding them. In order to expose certain of the fibres it is necessary to pass between the different branches of the vessels. The renal vein is in danger of being torn unless care is taken. Should this accident happen, a delicate suture should be used to close the opening. In all cases the kidney is fixed in position by flaps of capsule, and a small drain is placed at the lower end of the wound. The authors publish detailed accounts of six cases so treated, with complete relief in five. After this operation the patient suffers much more than after any ordinary operation on the kidney, even nephrectomy. There is, however, no urinary trouble, neither polyuria nor marked oliguria. Things are just as they are after any operation outside the urinary tract. In these patients specimens of urine taken from the enervated kidney differed little from those collected from its fellow of the opposite side.

In conclusion, it is apparent that the idea running through this address is that the pain we have been discussing is due in a large proportion of cases to distension of the renal pelvis. Treatment should be directed towards removing the cause, and involves, in some instances, ablation of the kidney. In selected cases it may be possible to relieve the patient by interrupting the nerves carrying the painful impressions.

## CERTAIN DISEASES OF THE COW AND THEIR INTEREST TO THE PHYSICIAN.\*

BY

FREDERICK HOBDAI, C.M.G., F.R.C.V.S., F.R.S.E.,  
HONORARY VETERINARY SURGEON TO HIS MAJESTY THE KING, AND  
FORMERLY PROFESSOR IN THE ROYAL VETERINARY  
COLLEGE, LONDON.

THE necessity for the medical man to be in touch with his veterinary colleague over the question of cattle disease is well illustrated by the fact that certain illnesses, some of which are fatal and all of which are troublesome, can be contracted from bovine animals, and occasions of this kind, where members of the two professions meet, cannot but lead to profitable discussions and interchanges of knowledge for mutual benefit. Foot-and-mouth disease, cow-pox, and ringworm are all of local interest to the practising physician, but have not the vital importance of tuberculosis and anthrax, the two diseases to which I propose particularly to divert attention to-night. Not that the others are not troublesome, but they are curable and only in rare instances cause death.

### Foot-and-Mouth Disease.

That foot-and-mouth disease is contagious to man has been demonstrated many times, but with proper precautions in connexion with the disposal of the milk the risk is comparatively slight. It is, however, one of the diseases in which the members of the veterinary profession occupy the front trench, and the risk of spread to man depends upon the efficiency of their organization.

Man can contract it by drinking infected milk or even by eating cheese or butter made from such sources. That those who handle the mouths and feet of the infected animals do not always escape is well illustrated by the following account, which is published<sup>1</sup> by Mr. Vincent Boyle, M.R.C.V.S., one of the Ministry of Agriculture veterinary inspectors.

A veterinary inspector was sent to deal with an outbreak of foot-and-mouth disease on a farm in Suffolk in November, 1920. His duty was to examine each animal, and he was in contact with diseased animals on four consecutive days, November 21st to 24th, 1920. On December 5th he fell ill, complained of headache and general malaise, and showed elevated temperature (101.4°). On December 8th vesicles appeared on the inner surface of the lips, and on the gums above and below the incisor teeth, and during the following three days up to December 11th further vesicles formed on the hard palate and tongue. His general condition became worse, elevated temperature persisted, there were periods of delirium and semi-consciousness, and the heart had by this time become affected with endocarditis, involving the valves, especially the aortic. By December 25th an improvement had set in, and the lesions in the mouth healed gradually. Improvement continued, though convalescence was prolonged.

The exact method of infection is not clear, but probably it was through particles of saliva, shed epithelium, etc., contaminated with virus, reaching the face and lips of the examiner during the examination of the mouth lesions of the affected sheep.

In England foot-and-mouth disease has not troubled the human practitioner very much, as immediately an outbreak amongst cattle is notified the Veterinary Department of the Ministry of Agriculture takes the animals and the premises in hand and imposes rigid quarantine precautions until all the affected and in contact animals are slaughtered; thus are prevented the sale of milk and the spread of the disease to man and other animals.

On the Continent, however, where the law is not so drastic, its contagiousness is well recognized, and during an outbreak in Oldenburg in 1920 an inquiry by the medical profession resulted in the establishment of some sixty definite cases in mankind. Again, on the authority of Hutya and Marek<sup>2</sup> we are told that Bussenius and Siegel report sixteen outbreaks occurring in man between 1878 and 1896, in the course of which entire families became affected, and that a number of cases ended fatally. This is enough to prove that the veterinary surgeon has his duty to perform and share in warding off this disease from man, and thus being of service to the medical practitioner.

### Cow-pox.

That cow-pox is contagious to man is well known to every owner of a dairy herd, and occasionally it causes severe constitutional as well as local symptoms necessitating cessation from work.

There is plenty of literature to prove its transmissibility, and a recent well illustrated article by Dr. R. J. Reece, C.B., read before the Royal Society of Medicine, "On the circumstances associated with an outbreak of disease amongst milch cows, horses, and their attendants, believed to be of the nature of cow-pox, in the county of Somersetshire in the year 1909," brought the subject recently to the fore again. The great interest which has recently been taken in the question of the communicability of disease from animals to man has brought a number of excellent clinical articles to the *Veterinary Journal*; as, for example:

Captain Sparrow, M.R.C.V.S., of Rochford, Essex, reported<sup>3</sup> an instance in which a dairy herd of 40 cows all had cow-pox, and "most of the milkers caught cow-pox, with lesions on their arms and hands, and had to be medically treated."

Mr. Hugh Begg, F.R.C.V.S., the chief veterinary inspector to the county of Lanark, reported cow-pox in a herd of 30 milking cows; the four milkers employed all developed typical pox lesions between the fingers and on the backs of the hands. The symptoms were sufficiently severe to keep them from duty for several days, and the sores did not heal for about three weeks.

Mr. E. J. Thorburn, M.R.C.V.S., of Crewkerne, Somerset, a very large dairy district, reported several outbreaks amongst the milch cows, and in one particular dairy, consisting of 60 cows (of which 20 became affected), three of the milkers became very badly inoculated. In two cases the men were very ill, and were under medical treatment for a considerable time. Starting between the fingers, the disease spread up the arm to the lymphatic glands and axilla, thence through the system to the glands in the lower extremities. Several weeks elapsed before the men became completely convalescent.

### Ringworm.

Ringworm, especially of the calf, is very readily transmissible and at some time or other bound to come under the notice of the practitioner in an agricultural district. Common in many districts, especially at certain seasons of the year, it is quite easy for the herdman who dresses the infected skins to contract the ailment. The veterinary practitioner is often himself a victim, and ringworm infection obtained from a calf is not so easily got rid of as the ordinary human variety. The head of a calf may be covered with the ringworm crusts, and one does not need to be more than slightly careless when handling calves with ringworm in order to find within a few days a practical proof of its contagiousness on one's own hands and arms.

That, too, it may be passed on is also a fact, and to illustrate that I cannot do better than quote a short clinical note Dr. Alfred Eddowes recently contributed to the *Veterinary Journal*:

"Thirty years ago, when I was practising in the country, a young woman consulted me one evening for what was obviously ringworm on her cheek. A number of questions were put to her as to how she had caught it. She was a parlourmaid and 'had nothing to do with children, ponies, cats, or calves.' I begged her to lock round on going home and send me word if she noticed anything like it. Next morning a man stepped into my consulting room. Seeing a ringworm on the centre of his forehead I merely asked his name and told him I could guess all the rest. He was cowman to Mr. C. of S— Park; that he had not been at the job long—was, in fact, quite a novice—otherwise he would have had a cap ready to wear while milking. Further, that he was in love with the pretty parlourmaid, and no wonder. 'Doctor, you know too much, but it's all true,' was his reply, and I almost fancied myself a Sherlock Holmes!"

### Anthrax.

The diseases to which I wish to draw special attention are anthrax and tuberculosis, and it is here that the collaboration of the medical and veterinary professions is so urgently desirable. Stamp out anthrax from the animal (especially the cow tribe) and from animal products, and it is eradicated from man, for its origin is always one or other of these sources. Stamp out tuberculosis from cattle and you do away with the deaths from bovine infection, caused mainly by the milk supply, which form quite a big proportion of the total, especially of the deaths of children. As illustrating this, and at the same time illustrating the value of collaboration, I will quote an extract from a clinical article which has just reached me, for publication in the *Veterinary Journal*, from Major Rabagliati, O.B.E., B.Sc., F.R.C.V.S., the Director of the Serum Institute for the Ministry of Agriculture in Egypt. He writes:

"Some years ago an outbreak of anthrax in some of the inhabitants in a certain village assumed considerable proportions. These cases came under the notice of the medical authorities, who instituted preventive isolation and quarantine, with the necessary treatment, amongst the affected people. It was noticed that most of the fatal cases occurred amongst the old women of the village,

\* An address given to the South Essex Division of the British Medical Association, December 6th, 1922.

and that they suffered from the pulmonary form of the disease. A few cases occurred in children, who had malignant pustules on the arms and legs, or even other parts of their bodies. The explanation of this difference of situation was not at once apparent. Although no cases in animals had been reported in this neighbourhood a Government veterinary inspector was sent to make inquiries. He found that both cattle and sheep had been dying, and also that a number of sick animals had been slaughtered illicitly, and was soon able to diagnose anthrax as the cause of the illness and deaths amongst the cattle and sheep.

"The cause of the symptoms was then clear, and was as follows: It is the custom of the villagers to collect cattle dung for fuel, and to make it into round cakes by drying it in the sun. This is usually done by the children. When dry it is used for cooking purposes, this being done by the older women.

"The children employed in collecting the dung, a lot of which was from the sick cattle, were not so much exposed, owing to the moisture, but occasionally contracted malignant pustules through abrasions; but the old women of the village, who broke up the sun-dried 'cakes,' talking as is usual all the time, inhaled the dust, rich in spores, and so fell ready victims to the pulmonary form of anthrax."

Anthrax has been very much to the front lately, and it has been rare for a week to pass without some notice in the public press either of a death in man or animal, or else drawing attention to the danger of infection. The Japanese shaving-brush scare did much to familiarize the man in the street with the risks he ran from non-disinfected goat hair and wool, and recently deaths have been reported from the wool-sorters' area. An International Advisory Committee has been formed, consisting of delegates from various parts of the world, to inquire into the disinfection of wool, hair, and skins infected with anthrax spores, and also into the practice and effective methods of preventing infection amongst flocks. The Committee is to report to the International Labour Conference in 1923, and there is no doubt that it will examine a large number of expert witnesses. Its preliminary meeting took place yesterday, and one of its first duties will be to inspect the new anthrax disinfecting station at Liverpool. This disinfecting station cost just over £110,000, and started operations in July, 1921. It is capable of disinfecting about 8 million pounds of wool annually, and it is estimated that by the expenditure of another £15,000 this output could be doubled.

Wool and hair are the chief carriers, and the workers in the Bradford district of Yorkshire know the first signs of woolsorters' disease quite well. It is estimated that by compulsory disinfection of all imported wool and hair the danger of anthrax infection to human beings will drop at once by 50 per cent.; and it is to be hoped that the talk which has arisen in regard to closing it down, on the ground that it has not paid its expenses during its first year, will not be allowed to materialize, as the mere expenditure of £5,700 should not be allowed to be considered when human lives are at stake. I am glad to be able to say that Dr. Hope, M.O.H. Liverpool, informs me that this excellent work is to continue.

Hides and skins are as important as the hair and wool, for they too may come off infected beasts, and all should be submitted to a disinfecting process, whether on arrival in England or at the port of embarkation. The latter is, of course, the more ideal as doing away with the chance of contamination of the ship, etc., by its cargo. Between July, 1921, and September 30th, 1922, about 1,280,000 lb. of material has been dealt with at the disinfecting station, and the wool-workers may reasonably look forward to the risk of their trade now being reduced to a minimum.

Bones, and bone manure, imported from infected countries must also receive attention, as also the question of cattle feeding cake, for in this we have a not uncommon source of trouble.

The killing of a dying beast and the subsequent risk of infection to the man who dresses the carcass can only be dealt with as the law directs. It is here that our two professions are likely to come in contact, and the medical practitioner should know when the danger exists in his neighbourhood. As regards the treatment, the medical profession has the advantage over the veterinary, in that anthrax in man is not so rapidly fatal as in cattle, and that Sclavo's serum is so valuable in man if injected in the early stages of infection.

With us, although we occasionally get reports of spontaneous recovery in the dog and pig, the disease in cattle and horses is generally fatal and comparatively rapid. Statistics of the Ministry of Agriculture show that the number of outbreaks of anthrax in animals in 1922 up to the week ending November 25th was 456, with a total number of 527 deaths—quite a considerable number when we remember that every one was

a possible centre of infection for a human being. This, added to the risk of infection from imported hair, hides, bone manure, feeding cakes, etc., all animal products, adds another disease danger to be grappled with and one in which the veterinarian again stands hand in hand with his medical colleague—for once get the animal aspect of the question clear the human side must automatically follow, and anthrax will be relegated to join glanders and rabies in the list of diseases with which the next generation will only be acquainted by hearsay.

#### Tuberculosis.

In the prevention of tuberculosis much good can be done by collaboration. Until the law is altered so as to compel the milk vendor to guarantee tubercle-free milk, so long shall we have the human deaths from bovine tubercle infection. Most things are sold as guaranteed free from adulteration, and why not that most essential of things—milk free from this contamination? Here one has a food, necessary to infants and invalids, and yet it may contain living cultures of the most insidious and terrible poison in the world.

Dr. Howarth, the medical officer of health for London, tells us that out of fifty consecutive samples of milk purchased in the city no less than one in four proved to be tuberculous; and Dr. Bigger, at the last meeting of the Statistical Society of Ireland, asserted that 6 per cent. of all deaths from tuberculosis were due to drinking tuberculous milk. When we know it is preventable we cannot understand why no move is made.

At the recent National Milk Conference, Dr. Stanley Griffith, in a paper on bovine tuberculosis and its relation to man, gave some statistics which went to prove more than ever the necessity for the medical and veterinary branches of medicine to pull together.

In an investigation on 1,200 cases of human tuberculosis, "out of 116 cases of cervical gland tuberculosis it was found that 87.5 per cent. of those under 5 years were bovine, 61.3 per cent. of those between 5 and 10 years, 37.9 of those between 10 and 16, and 25 per cent. of those 16 years or over. Of 476 cases of bone and joint tuberculosis, 28.7 per cent. of those under 5 years were bovine, 23.1 per cent. of those between 5 and 10, 9.5 per cent. of those between 10 and 16, and 6.4 per cent. of those over 16. Of 126 cases of lupus, 69 per cent. of those under 5 years were bovine, 42.5 per cent. of those between 5 and 10, 60 per cent. of those between 10 and 16, and 17.6 per cent. of those over 16. Of 52 cases of scrofuloderma 58 per cent. of those under 5 were bovine, 44 per cent. of those between 5 and 16, and 7.7 per cent. of those over 16. Of 17 cases of genito-urinary tuberculosis, 3 were found to be bovine in origin. Of 113 post-mortem examinations conducted for the Local Government Board, it was found that in 21.3 per cent. of those under 5 years at death the infecting bacilli were bovine, and in 13.4 per cent. of those where death occurred between 5 and 12 years. From these and similar data it was estimated that bovine tuberculosis caused 6.44 per cent. of all the deaths from tuberculosis in England and Wales, or approximately 3,000 deaths every year. Both types of bacillus were equally virulent for man, the mode of entry being an important factor in determining the severity of the disease. Thus the effects of alimentary infection are, as a rule, less severe than those of respiratory infection. The age incidence and anatomical distribution of the primary lesions clearly point to cow's milk as the source of infection with the bovine type. Cows with tuberculous udders are the most dangerous, but cows with advanced tuberculosis may yield tuberculous milk or infect the milk through infected faeces or uterine discharges."

Why is not the 1914 Cattle Tuberculosis Order reimposed? Why are we not compelled to test the milking cows and segregate or eventually fatten or destroy the reactors, marking them in such a way that it cannot be deleted or passed by? This would at the least do away with a big proportion of the risk of infection, and probably indirectly abolish many other ailments which gain their foothold when the powers of resistance are depleted.

It is true that the scheme needs to be financed in order to pay the necessary compensation, but it seems incredible that money should be allowed to stand in the way of human lives and health.

Dr. Nathan Raw's scheme of vaccine immunization is being tried in various pedigree herds. Unfortunately it takes time to get results, but if this proves successful it will be a boon beyond price to the bovine race, and indirectly through the cattle to man, and a still further link in the chain of collaboration between the two professions.

## DISCUSSION.

Lieut.-Colonel T. D. Young stated that the City of London Public Health Department presented a good example of the collaboration between the medical and veterinary officers. Dr. Collingridge, with keen foresight, recommended some years ago that the officer in charge of meat inspection should be a veterinary surgeon, and the City Corporation adopted his suggestion. The appointment was followed by the issue of by-laws to regulate the hours of slaughter; any killing proposed to be carried out after regulation hours was to be notified by the butchers, and no carcass or offal was to be removed until inspected. Statistics showed the marked results as to efficiency. Following the improvement of slaughterhouses came the more scientific inspection of pig carcasses, whereby £50,000 was saved in 1915 in the central markets, and the Departmental Committee on Meat Inspection recommended the adoption by local authorities of similar by-laws and the same system of examining pig carcasses as to their fitness for human food. Colonel Young gave instances of the finding of dead animals in lairages, the rapid examination of the blood, and the diagnosis of anthrax, whereby danger to slaughtermen and drovers was prevented. Dr. W. J. Howarth, the medical officer of the City, was not less anxious that progress should be made in all matters relating to the purity of meat and milk supply. In the speaker's opinion no public health department was complete without a veterinary officer collaborating with the medical officer in controlling and supervising meat inspection, inspection of cows and cowsheds, contagious diseases of animals, and the care of the authorities' horses. The salary (paid by the various committees) would be well spent in the interests of the public; he urged the reintroduction of the Cattle Tuberculosis Order and the sterilization of all milk or milk products to calves and pigs, as is done in Holland and some other countries. Figures were given showing the splendid results obtained.

## THE SCIENTIFIC BASIS FOR NON-SPECIFIC PROTEIN THERAPY.\*

BY

A. J. CLARK, M.C., M.D., F.R.C.P.

(From the Pharmacological Department, University College, London.)

THE clinical successes obtained with non-specific protein therapy have attracted great attention, particularly in America and Germany. Unfortunately the scientific foundations for this method of treatment are very uncertain. The present paper is an attempt to collect the available scientific evidence showing the nature of the effects produced by non-specific protein therapy. It is important to remember that this method of treatment developed along purely empirical lines from specific treatment with serums and vaccines. The minds of clinical workers were strongly prejudiced in favour of the view that such treatment to be effective must be specific; nevertheless, in spite of this preconception, it was established that in many cases non-specific vaccines and serums were as active as specific, and it was discovered that a large assortment of proteins and products of protein breakdown produced the same effects as vaccines; intravenous administration, moreover, was found to be a particularly effective method of administration.

Non specific protein therapy has been recommended for the majority of known diseases, but there is fairly satisfactory evidence that it is of benefit in the following classes of cases.

1. *Acute general infections*—for example, typhoid fever; here, after an initial exacerbation of the fever, it frequently causes it to terminate abruptly by crisis.

2. *Chronic infections with local lesions*; in this case the injection causes a febrile reaction, which is followed by a secondary phase in which there is a feeling of bodily well-being. The local lesions during the febrile reaction show acute inflammation, and subsequently healing is accelerated in many cases.

Non-specific protein therapy has been particularly successful in the treatment of arthritis, both acute and chronic, in gonorrhoea, in typhoid fever, and in anthrax.

The reaction obtained in non-specific protein therapy depends upon the agent administered and the manner in which it is administered; the general characters of the febrile reaction appear to be essentially the same whatever agent is employed. The

tration of typhoid vaccine are familiar to all, and may be taken as a type.

The intravenous injection of vaccines produces a more rapid and more severe response than the hypodermic administration. Peptone administration produces a less violent reaction than vaccines, and it is much easier to get peptones of standard activity than vaccines of standard activity. Purified proteins are usually given by intramuscular injection; they produce a mild reaction after a delay of some hours.

### Reagents Used in Non-specific Protein Therapy.

- (a) Proteins—for example, purified casein (caseosan, aolan).
- (b) Mixtures containing proteins—for example, milk, normal serum.
- (c) Products of protein breakdown—for example, purified proteoses, commercial peptones.
- (d) Other preparations containing products of protein breakdown—for example, some commercial preparations of colloidal metals, polyglanular extracts, etc.

A febrile reaction similar to that produced by protein therapy often follows a large number of other therapeutic measures, and Bier<sup>1</sup> is of opinion that any measure which causes breakdown of body proteins produces therapeutic results similar to the injection of proteins. According to this view the following procedures may be classed under the same heading:

- (a) Intravenous injections which produce alterations in the blood proteins—for example, hypertonic and hypotonic solutions, protein precipitants such as mercury perchloride, and many other disinfectants.
- (b) Radium, x rays, and the cautery and other procedures which lead to the destruction of body cells.

### The Action of Non-specific Protein Therapy on Infections.

It may be stated at once that there is very little evidence that protein therapy has any effect upon the course of infection in laboratory animals. As a whole the laboratory evidence fails to confirm the clinical evidence.

For example, Bingel<sup>2</sup> treated 471 cases of diphtheria with diphtheria antitoxin and treated an equal number of alternating cases with normal horse serum, and found that there was no difference in the mortality rates. Meyer<sup>3</sup> found that normal horse serum only saved 33 per cent. of guinea-pigs from a minimal lethal dose of diphtheria toxin, and Cowie and his co-workers<sup>4</sup> showed that the mild protective effect produced by horse serum was due to its containing traces of diphtheria antitoxin, and that other serums had no such effect. This, therefore, is not a case of non-specific protein therapy.

Normal ox serum has been used extensively in anthrax, and Kraus<sup>5</sup> found that it protected laboratory animals from anthrax, but other workers<sup>6</sup> have had negative results. Weichardt<sup>7</sup> obtained favourable results by treating mice infected with pneumococci with non-specific proteins, but Kross<sup>8</sup> had completely negative results with this treatment in rats infected with mouse typhoid.

One common criticism may be made of most of the above-mentioned results—namely, that the protein reaction varies greatly in different species, and that since rabbits, rats, and mice are peculiarly insensitive to protein shock they are unsuitable material upon which to test the results of protein therapy.

### The Substance Producing the Protein Reaction.

Since injections both of proteins and of products of protein breakdown and the destruction of body cells all produce a similar reaction, it appears probable that the common active principle is a product of protein decomposition.

Vaughan has shown<sup>9</sup> that the heating of protein with alkali in alcohol produces an intensely toxic product of which 0.5 mg. is sufficient to kill a guinea-pig. This substance appears to be a proteose; it gives the biuret reaction, it diffuses slowly through collodion membranes, and it is freely soluble in absolute alcohol, although insoluble in ether. When proteins are hydrolysed the higher cleavage products are toxic. The toxic effects produced by such preparations as Witte's peptone are well known, but it is important to note that so-called peptone poisoning is produced by proteoses and albumoses, and that proteins, when broken down completely to peptones, have very little toxicity.

Commercial peptones contain various bodies soluble in alcohol which have interesting pharmacological actions on isolated organs, but these substances are not highly toxic; heating with acid or alkaline alcohol produces, however, a strong poison which has all the characters of Vaughan's soluble protein poison. This substance was named "vasodilatin" by Popielski.<sup>10</sup> I measured the toxicity of peptones

by intravenous injections into mice, and found that 1 gram of Witte's peptone yielded about 0.3 gram of vaso-dilatin, and that the minimal lethal dose of the peptone was 4 mg. per gram of mouse, while the minimal lethal dose of the vaso-dilatin was 0.1 mg. per gram. This experiment shows that the vaso-dilatin cannot be performed in the peptone, although it appears to be formed more readily from peptone than from protein.

The base histamine produces effects similar to peptone poisoning, and it has been suggested that the toxic actions of peptones are due to histamine. Hauke and Koessler<sup>11</sup> showed that the content of Witte's peptone in histamine was not more than 3 mg. per 100 grams. I found that histamine was practically non-toxic to mice, which survived intravenous doses up to 0.3 mg. per gram. Histamine cannot therefore be the active principle of vaso-dilatin or of peptones.

The effects produced by peptones, protein poison, and histamine are very similar, although the reactions in different species of animals vary greatly. These varying effects in all cases closely resemble the symptoms of anaphylactic shock. The chief features of the reaction produced by these products of protein breakdown are as follows:

- (a) A rise of temperature associated with an increase of nitrogenous metabolism.
- (b) Contraction of plain muscles.
- (c) Increased secretion of glands.
- (d) Increased permeability of the capillaries, particularly of the liver capillaries.

The effect of intravenous injections of peptones in dogs is to cause a rapid fall of blood pressure, associated with a great swelling of the liver and rise of portal pressure. The peptone appears to act as a poison to the liver capillaries, and thus causes the liver to be engorged with blood; this prevents a proper return of blood to the heart, and consequently a fall of blood pressure, and at the same time a great increase in the lymph flow. The blood becomes non-coagulable and the animal is rendered immune to a subsequent injection.

Peptones have only a slight toxic action on rabbits, rats, and mice, and have no strongly toxic action on guinea-pigs. Vaughan's soluble protein poison produces the same effects as peptones in cats and dogs, but also acts as a strong poison to the other animals mentioned. Histamine has the same general action as peptones, but it does not render the blood non-coagulable, does not increase nitrogen metabolism, and does not produce immunity. Maunier and Pick<sup>12</sup> found that peptones and histamine produced engorgement of the isolated liver of the cat, dog, and ape, but had no such action upon the livers of rodents. The action of these poisons on skin capillaries can be demonstrated very easily by applying them endermically, when they produce wheals.

#### The Mode of Action of Protein Therapy.

The evidence considered makes it easy to understand why a large number of different procedures, all tending to introduce into the blood products of protein breakdown, should have a similar pharmacological effect. It is more difficult to understand why such reactions should produce therapeutic benefit.

There is no doubt that an excess of protein breakdown products is violently toxic. Besides the evidence from animals, we have the clinical evidence regarding traumatic shock, which appears to be caused by protein breakdown products. Whipple, moreover, has shown that the toxæmia produced by acute intestinal obstruction is due to the absorption of toxic proteoses.

All who have studied non-specific protein therapy emphasize the necessity of grading doses correctly, and agree that an overdose is extremely dangerous in its immediate effects, and does damage in its ultimate effects. The reaction, therefore, will only produce benefit if it is of a certain strength.

Weichardt<sup>13</sup> explains the effect of protein therapy by saying that it causes "omnicellular plasma activation." Other observers state that protein therapy establishes a condition of vagotonia. In this connexion it is interesting to note that Rosenthal and Holzer<sup>14</sup> and Freund and Gottlieb<sup>15</sup> found that protein therapy caused an increased sensitivity to adrenaline and pilocarpine in experimental animals. There appears to be no obvious explanation for this phenomenon.

#### The Blood Changes Produced by Protein Therapy.

The most important effect of protein therapy appears to be to produce an immediate negative phase with increased permeability of the capillaries, followed by a positive phase with decreased capillary permeability. The chief effect of the increased permeability is an increased lymph flow which washes into the blood stream a large variety of products of

cell metabolism. Heidenhain first showed that peptones and various proteoses caused increased lymph flow, and numerous writers have confirmed this. Petersen<sup>16</sup> showed, for instance, that in a dog typhoid vaccine induced increased lymph flow. Starkenstein<sup>17</sup> studied the rate of excretion of fluorescein into corneal ulcers, and concluded that non-specific protein therapy at first caused increased permeability of capillaries and later decreased permeability. Luthilen<sup>18</sup> measured the rate of excretion of iodides and ferrocyanides into the peritoneal cavity in the rabbit, and concluded that protein therapy caused decreased permeability of the capillaries. Starkenstein<sup>17</sup> and Döllken and Herzger<sup>19</sup> found that protein therapy diminished the toxicity of strychnine to rabbits.

There is no doubt that the protein cleavage products have a strong lymphagogue action and produce increased permeability of the capillaries, particularly in the liver and in the skin. The last effect is shown by the readiness with which they produce urticaria. Whether the capillaries really become less permeable than normal during the positive phase of the reaction appears to the writer a little doubtful. The blood changes observed are as follows:

- (a) Immediate leucopenia, followed by leucocytosis (Gow<sup>20</sup>); during the latter stage an increased number of young and atypical red cells and an increased number of platelets are present (Cowie and Calloun<sup>21</sup>).
- (b) There is an increase in the fibrinogen, globulin, thrombo-kinase, and blood sugar content in the blood.
- (c) The non-protein nitrogen content of the blood is raised considerably (Van Slyke and Whipple<sup>22</sup>).
- (d) The proteolytic ferments in the blood are increased (Jobling and Petersen<sup>23</sup>).
- (e) The antibodies in the blood are increased.

There is a general agreement as to the occurrence of these changes, but the relative importance of the changes is a matter of dispute. Jobling considered that the alterations in the content of the blood in proteolytic ferment was of great significance, but this is denied by Teale and Bach<sup>24</sup>. The increase in antibodies only occurs if an animal has been previously immunized. Apparently new antibodies are not formed, but antibodies present in the tissues are washed back into the blood.

The anaphylactic state depends upon the presence of antibodies in the tissues and their absence from the blood, and it is interesting to note that peptone injections cause a temporary desensitization in sensitized animals (Kellaway and Cowell<sup>25</sup>). Observations on typhoid patients show that only a slight rise in agglutinin content of the blood is produced by protein therapy, and most observers agree that it is quite insufficient to account for the beneficial effects produced by protein therapy in this disease.

The diphasic action produced by protein therapy is confirmed by Dresel and Freund<sup>26</sup> who found that in cats caseous injections caused at first the appearance of a dilator substance in the blood, and that after a few days a vaso-constrictor substance appeared. A vaso-constrictor substance can be obtained from blood platelets, and the platelets probably furnish the vaso-constrictor substance which appears when blood clots; but vaso-constrictor substances can be obtained from most tissues of the body, and therefore the origin of the substance found by Dresel and Freund is uncertain: it is certainly unnecessary to assume that it is a product of platelet breakdown.

These changes observed in the blood are of great interest, and the bulk of the evidence points to the fact that non-specific protein therapy causes a washing out of the tissue fluids into the blood, and that this process causes a number of changes in the composition of the blood. Unfortunately the evidence at present available is insufficient to indicate which of the changes observed is really of chief clinical importance.

## DIASTASE IN BLOOD AND URINE IN DIABETES MELLITUS.

BY

G. A. HARRISON, B.A., M.B., B.Ch. Cantab.,\*

AND

R. D. LAWRENCE, M.D. ABERD.†

(From the Biochemical Laboratory, King's College Hospital, London.)

In a previous paper<sup>1</sup> we have published some of our work on blood amylase, and have reported our findings in normal individuals and in renal disease, illustrating the importance of estimating diastase in both blood and urine. In this paper we shall outline our findings in pancreatic cases, in hepatic disease, and in diabetes mellitus, and then discuss the results in diabetes with reference to pancreas, liver, and kidney. Throughout this investigation the reaction of the urine has been adjusted to  $P_H$  6.7 before estimation of amylase, unless otherwise stated.

A brief summary of our previous results will facilitate comparison with the findings in diabetes.

Normally, the concentration of diastase in the blood lies between 3 and 10 units, and in the urine between 6.7 and 33.3 units. The total quantity of diastase excreted in twenty-four hours varies from 8,000 to 30,000 units. It is useful to calculate the total diastase excreted to reveal instances in which high or low concentrations of diastase may legitimately be attributed to oliguria or diuresis.

In renal disease there may be (a) "diminished excretion with retention," in which the value for blood is above 10, and for urine below 6.7; (b) "diminished excretion without retention," in which the blood amylase is normal, but the concentration in the urine is lower than in the blood or of the same value; (c) "normal excretion," in which the concentration of diastase is higher in the urine than in the blood.

TABLE I.—Examples of Results in Diseases of Pancreas and Liver.

Case.	Blood Diastase.	Urine (24 hours).			Remarks.
		Concentration of Diastase.	Vol.	Total Diastase Excreted.	
	units	units	c.cm.	units	
A	23.5	16.7	3,900	65,100	Gunshot wound of pancreas; resulting cyst drained.
5	3.3	2,780	9,200		Three weeks later, clinically much improved.

Note.—The reaction of the urine was not adjusted to optimum  $P_H$  except in Cases E and F. The total diastase excreted in twenty-four hours is calculated to the nearest hundred. Case F is included for comparison.

\* Working on diabetes with a grant from the Medical Research Council. Part of this work was included in a thesis for the degree of Doctor of Medicine, Aberdeen, 1922.

## Pancreatic Disease.

It is well recognized that active destruction of the pancreas (or sudden obstruction of its ducts) is accompanied by an increased concentration of diastase in the urine, and usually in the blood also. Examples are given in Table I. Occasionally a moderately high concentration of urinary diastase may be found in the absence of any other evidence of pancreatic disease (Case F, Table I).

We conclude that a high urinary index, when accompanied by a raised blood diastase, is diagnostic of active pancreatic disease, but when accompanied by a normal value for blood is merely suggestive.

## Liver Disease.

The urinary and blood diastase in the majority of 20 patients has been within normal limits. The blood diastase was subnormal in three cases (all severe), but these low values were accompanied by normal urinary figures for the concentration and total excretion of diastase. In two patients the blood diastase rose as the jaundice and clinical condition improved (Table I).

## DIABETES MELLITUS.

## Blood Diastase.

Over 200 estimations have been made in a series of 48 patients. In one instance only was the value raised (13.3 units), the estimation being made six hours before death in coma. Fourteen patients had a subnormal blood amylase (1 or 2 units). These low figures have been obtained usually, but not invariably, before treatment or during fasting or on low diets. In many instances they have been accompanied by normal values for concentration or total excretion of diastase in the urine.

In a few cases estimations of blood diastase at intervals of several days or weeks have revealed slight variations, the maximum being 5 units. We have been unable to correlate such changes with the clinical condition, the blood sugar content, or the diet (Table II), and are inclined to regard them as of little or no significance.

In our previous paper<sup>1</sup> it was pointed out that blood diastase remains virtually constant throughout the day (estimations at hourly or half-hourly intervals) in normal individuals and in diabetes mellitus. The following are typical experiments in diabetics:

Case S.—Mild. Blood diastase and blood sugar estimated at 10.15 a.m., immediately before a dose of 50 grams of glucose, taken fasting, and again at hourly intervals until 5.15 p.m. Lunch 1 to 1.15 p.m., and tea 4 to 4.15 p.m. The blood amylase was 5 units on each of the eight occasions. The blood sugar was 0.10, 0.21, 0.14, 0.11, 0.09, 0.07, 0.08, and — per cent. respectively.\*

\* The — signifies not estimated.

Although the blood sugar was doubled the diastatic-index remained constant.

**Case 7.**—Severe. Examinations before, and at half-hourly intervals after, a meal consisting of carbohydrate (30 grams), protein (23 grams), and fat (13 grams). The serum diastase was 3, 3, 4, 3, 3, and 3 units. The blood sugar was 0.215, 0.27, 0.23, 0.25, 0.27, and 0.27 per cent.

#### Urinary Diastase.

Until recently the reaction of the urine has been disregarded in estimating the concentration of diastase. Dodds<sup>2</sup> and Sladden<sup>3</sup> have published papers showing that a very considerable error may be introduced if the reaction is not adjusted to the optimum for the enzyme. This fact will necessitate the repetition of much of the work on urinary diastase, and accounts for many of the low results reported, but not for all. We append a few of our most striking figures to show the importance of this adjustment, in confirmation of the findings of the above workers (Table III), together with a few instances in which such correction has made little or no difference. Our corrections have been made according to the plan suggested by Sladden. The reaction has been adjusted with decinormal soda or hydrochloric acid to P<sub>H</sub> 6.7, the dilution being allowed for in the subsequent calculation. One per mille soluble starch in 0.5 per cent. sodium chloride has then been added in the usual way.

\* Night urine.

Several hundreds of estimations of the concentration and total excretion of diastase have been made in a series of 55 diabetics, but only in 20 patients has the reaction of the urine been adjusted. Our remarks on diminished diastase excretion naturally are based solely on the corrected results.

In nearly all diabetics at one time or another the diastatic index is subnormal owing to polyuria, the total excretion being normal. But both concentration and excretion have been subnormal in 4 out of the 20 cases. We attribute such findings to a general depression of metabolism. Raised values have been encountered in only two patients, and then only in a minority of a large number of estimations.

**Case 26.**—Blood diastase 2 to 6.7 units (6 tests); urinary diastase, concentration 3.3 to 26, and excretion 10,300 to 40,800 units (43 tests, of which only 9 exceeded 30,000).

**Case 42.**—Blood diastase 4 to 10 units (4 estimations); urine, concentration 8 to 33.3, and excretion 14,400 to 69,900 units (62 estimations, of which 23 exceeded 30,000). The reaction of the urine has been corrected in all these experiments.

The influence of diet has been studied fully in eight patients. Before we realized the importance of correcting the reaction

of the urine, it was concluded that the excretion of amylase was generally lowered by fasting or by very low diets. We have repeated our experiments in three patients, making the necessary correction, and have made similar observations on two new patients, the P<sub>H</sub> of whose urine was adjusted in the first instance. As a result we now conclude that no marked or constant change in diastase excretion can be demonstrated as a direct consequence of changes in diet (Table IV).

\* Exploratory laparotomy (spinal anaesthesia, gas and oxygen), October 5th, 1922; nothing abnormal found.

† Two teeth extracted under gas, November 7th, 1922.

No evidence has been obtained for associating our diastase results in diabetes mellitus with kidney inefficiency. In no instance has there been "diastase retention" (with a single possible exception, blood amylase 13.3 units, urine not examined). Four patients have exhibited "diminished excretion without retention" of the ferment on one or more occasions (the reaction of the urine had been adjusted to P<sub>H</sub> 6.7). This diminished excretion may have been due to a general depression of metabolism. Clinically there was no evidence of renal inefficiency and urea tests of renal function were normal.

Increase of diastase in blood or urine has been reported only in active destruction of the acini of the pancreas. It is not surprising, therefore, that the majority of diabetics do not show raised amylase values. Their islet tissue may be degenerating as a result of overstrain by excessive diet (Allen), but in the absence of destruction of acini an increase of diastase excretion would not be expected. Conversely, when raised diastase values are found in diabetics, they might be regarded as evidence of active pancreatic injury (inflammatory or otherwise). Only two of our cases have shown such increases, and these were transitory and relatively small. The highest figures found were: blood diastase 10 units; urine, concentration of diastase 33.3 units, volume 2,100 c.c.m., and total diastase excreted 69,900 units.

In connexion with their work on the CO<sub>2</sub> content of alveolar air, Bennett and Dodds<sup>4</sup> have made an alternative suggestion—namely, that in diabetes mellitus there may be an excessive flow of pancreatic juice, with a corresponding diminution in internal secretion. It is true that we have not estimated diastase in the faeces, but the great majority of our cases (including many that clinically were severe and untreated at

the time) show either a normal or a diminished amylase content in blood and urine. Our work therefore gives little or no support to this hypothesis.

So far we have found a subnormal blood diastase only in diabetes mellitus, liver disease, one case of albuminuria in pregnancy (Table III, K632), and one case of septic endocarditis. In most instances the urinary diastase was normal, so that the low blood values were not due to a diminished formation of the ferment. It is possible that a lowered renal threshold for amylase was present, such as has been suggested by Langdon Brown\* to explain the relatively high urinary figures (associated with normal blood diastase) in pregnancy toxæmias. Excluding the pregnant patient, our cases had little or no albuminuria. Otherwise we are at a loss as to what significance (if any) should be attached to these subnormal blood amylase findings.

In conclusion our results confirm the opinion of previous investigators (Allen†) that diastase tests are of little or no value in the diagnosis, prognosis, or treatment of diabetes mellitus.

#### Summary.

Estimations of diastase simultaneously in blood and urine have been made in fifty-five diabetics and a large number of controls, due attention being paid to the reaction of the urine, the diet, etc.

Our findings are in support of those investigators who have concluded that the presence of amylase is more or less accidental, and of little or no value in the diagnosis, prognosis, or treatment of diabetes mellitus.

## BRACHIAL NEURITIS DUE TO CERVICAL RIB.

BY

W. WRANGHAM, O.B.E., M.D., M.R.C.P.,  
HONORARY PHYSICIAN, BRADFORD ROYAL INFIRMARY;

AND

JAMES PHILLIPS, F.R.C.S. EDIN.,  
HONORARY SURGEON, BRADFORD ROYAL INFIRMARY.

MUCH has been published on the condition of cervical ribs and the symptoms which this abnormality may produce, but most of the articles have been contributed to meetings of specialists or to little read journals, and a pathological condition does not become common knowledge until it has been repeatedly brought to the notice of the general practitioner at meetings of societies which he attends or in journals which he reads.

#### HISTORICAL.

In 1893 Lewis Jones published a report of 6 cases of paralysis of the small muscles of the hand (some supplied by the ulnar and some by the median nerve), which did not progress and so differed from progressive muscular atrophy.

In 1902 Buzzard published a series of similar cases and diagnosed the condition as due to a lesion of an individual root of the brachial plexus, but was puzzled as to the cause.

Apparently neither of these physicians was aware that in 1891, at Edinburgh, Sir David Wallace had read a paper in which he reviewed the older (anatomical) literature on cervical ribs, and had shown a patient with pressure symptoms which Wallace attributed to a rudimentary cervical rib.

In 1895 Stiles recorded a case of his own and referred to 8 or 10 cases in which the cervical rib had been excised.

Thorburn was probably the first to use x rays to diagnose the presence of rudimentary ribs, and in 1904 he described before a London society two cases with pressure symptoms.

The connexion between the nerve symptoms and cervical ribs having thus been brought to his notice Lewis Jones endeavoured to trace the cases he had described eleven years earlier, and found that of 14 patients examined 10 showed one or more cervical ribs.

Edwin Bramwell was apparently the first to suggest (in 1903) that the lowest brachial plexus root might be pressed on by a rudimentary or even by a normal first thoracic rib, and in 1911 Sir Harold Stiles removed a portion of first rib, with satisfactory result, from a patient with typical pressure symptoms. Similar cases have been recorded by various surgeons (Stopford stated in 1919 that in less than two years he had met with 10 cases of compression neuritis

produced by normal first rib), but, so far from this having become common knowledge, Stiles informs us that it was news to not a few of the American surgeons to whom he lectured on the condition in the States in 1922.

#### EMBRYOLOGY.

In a limbless animal like the snake, to every vertebra is attached a pair of ribs, and each somatic segment has also its pair of segmental nerves. In the human embryo the arms and legs first appear as limb buds, the arm bud springing from five or six vertebral segments. These segments grow chiefly in a vertical direction, while the limb grows chiefly out at right angles and soon fails to cover the whole vertical extent of the segments from which it was derived. Thus, of the spinal nerves which supply the limb, the upper and lower nerves come to pass more and more obliquely between their points of origin and their point of entry into the limb. The nerves are relatively larger in the embryo than after birth, and they are of sufficient size to interfere with the forward growth of the rib mesoblast, so that in the cervical and lumbar regions the ribs are normally represented by the rudimentary costal processes of the vertebrae only. Occasionally a more or less perfectly formed pair of ribs spring from the seventh cervical vertebra; more rarely the first pair of thoracic ribs are incomplete or rudimentary. The limb bud is not constant in its origin: in some individuals it derives from the cervical segments alone, in others it derives also from the first dorsal segment, and exceptionally from the second dorsal segment also. The brachial plexus, being of course formed from the nerves of whichever segments enter into the origin of the limb, varies accordingly. Wood Jones states that where little or no contribution to the plexus comes from the first dorsal root there is a greater liability to cervical rib; in cases of rudimentary first rib the second thoracic nerve has been found to make a considerable contribution to the brachial plexus.

#### ANATOMY.

A rudimentary cervical rib is commonly an inch or more in length, and ends in a rounded knob from which a tight fibrous band passes to be attached to the first rib. An intercostal muscle exists between the rudimentary rib and the rib below; anteriorly the muscle fibres are gradually replaced by fibrous tissue. The lowest root of the brachial plexus more usually passes over and rests upon this fibrous band than upon the rudimentary rib itself.

#### CAUSE OF SYMPTOMS.

Cervical rib is of course a congenital condition. Pressure symptoms rarely occur before adult age. This is explained by the dropping of the shoulder which normally takes place as growth proceeds: in the child the clavicles rise markedly from their sternal ends towards their outer extremities; in adults (especially women) they not uncommonly slope downwards from their sternal ends. Apart from this general factor, there is almost always a definite exciting cause for the pressure symptoms. This may be an acute illness—for example, diphtheria—leading to stretching of ligaments; or a sudden weight lifting; or the pressure, say, of a violin above the clavicle; or unaccustomed use of the upper limb, strenuous such as digging, or intricate such as piano playing or typewriting.

#### SYMPTOMS.

The lowest root of the brachial plexus contains motor, sensory, and sympathetic fibres, and motor, sensory, trophic, and vascular symptoms may all be present in cases of rib pressure.

**Pain.**—The patient most usually consults a doctor on account of pain, which commonly extends along one aspect (more often the inner side) of the forearm. The pain is burning, neuralgic, or "pins and needles" in character, and a diagnostic point of importance is that it is relieved by raising the arm above the head, this movement lifting the nerve off the rib or fibrous band over which it has been stretched.

**Paralysis.**—Wasting of the thenar eminence is the most frequent motor symptom, the opponens pollicis and abductor pollicis being the muscles usually chiefly affected. Careful examination may reveal wasting of some of the interossei or others of the ulnar group of muscles, but the most characteristic clinical picture is one where there is very obvious wasting of the ball of the thumb.

**Vascular Symptoms.**—A weak radial pulse has been not uncommonly noted; very rarely oedema of the forearm.

**Trophic Symptoms.**—Gangrene of the fingers is a very rare symptom.

## TREATMENT.

The symptoms being due to pressure on a nerve root, they cannot be cured except by removing the pressure, and this can only be done by surgical operation.

In the absence of pain it is doubtful whether a patient should be urged to submit to operation merely on account of paresis of some of the intrinsic muscles of the hand unless his occupation is one which requires the use of these muscles. But the doctor is hardly likely to be consulted unless there is pain; if he finds that pain in the hand or forearm is relieved by raising the limb above the head, and is accompanied by thenar wasting, he should have the patient x-rayed; and even if no cervical rib is found to be present the characteristic syndrome will justify a diagnosis of rib pressure and warrant recourse to operation.

The operation is a dissection of the neck, demanding an accurate knowledge of anatomy; if a cervical rib is present it is isolated, divided posteriorly, and removed. If no cervical rib is present a portion of the first rib is removed. Provided the symptoms have not persisted too long cure is to be expected—usually rapid cure of pain and much less rapid restoration of muscle power.

The case which we have to describe came under the care of one of us (W. W.) on March 16th, 1922.

He was a well developed, muscular young man of 25, living in the country, who had previously been in good health. Five months ago he began to have pain in the back of the right wrist; later it spread to the arm, and a fortnight ago the right side of the root of the neck became painful. The pain was intermittent, and he might be free from it for two or three hours at a time; but when present the pain was severe and burning, and at night prevented sleep. He found some relief from supporting the elbow. On examination, the pad of the forefinger was dry and black, and there was a smaller area at the tip of the thumb, and a quite small black spot on the tip of the middle finger. The right thenar eminence was smaller than the left, and the muscles of the right forearm had less tone in them than those in the left. Sensation was impaired in the thumb and forefinger.

Palpation at the root of the neck revealed on both sides a hard bone-like outgrowth, suggesting an extra rib, which was confirmed by a skiagram. The sensory impairment and trophic changes at the tips of the thumb and first and second fingers pointed to involvement of the sixth or sixth and seventh cervical nerves, and the slight wasting of the thenar eminence showed that the eighth cervical had not wholly escaped.

On inquiry as to a possible cause for the development of the symptoms the man stated that he had been digging rather vigorously in his garden for many days prior to the onset of the pain.

**Operation.**—On March 28th, 1922, through an L-shaped incision the right cervical rib was exposed and divided posteriorly and removed.

**Result.**—The operation was followed by immediate relief of pain. The trophic changes cleared up less quickly and the gangrenous tip of the forefinger had ultimately to be amputated.

Writing on October 25th, 1922, the family doctor thus describes the man's condition: "There is slight tenderness at the corner of the scar to the ulnar side—this has always been the tenderest spot. No anaesthesia or pain in forearm or hand. No trophic changes except that the terminal inch of the forefinger is slightly red, glazed, and numb. The muscles of the forearm are like a blacksmith's, very well developed, and there is no difference between those of the right and left hands except as regards the thumb muscles."

## ASTHMA AND ADRENAL INADEQUACY.\*

BY  
T. DRUMMOND, M.D., M.R.C.P. EDIN.,  
DURBAN, SOUTH AFRICA.

I do not propose to enlarge in any detail on what we one and all picture to ourselves as asthma, and what we readily recognize as such, but there are a few points I should like to refer to.

Dienlaffoy, in his description, says: "The attacks of dyspnoea which constitute asthma . . . appear suddenly, weeks, months, or even years apart." They consist of two elements—(1) a nervous, which is constant, and (2) a catarrhal, which is variable, may not be present with first attacks, but appears as a complication in later attacks. The attack of asthma generally begins "in the early hours of the night." Then follows a picture of the patient during a paroxysm:

"An attack of asthma is rarely single; we usually see a series of attacks which are repeated for several days or weeks; they often return at the same hour—usually at night. . . . Analysis of the attack shows that the dyspnoea presents peculiar characteristics. . . . The painful and wheezing inspiration

only allows an insufficient quantity of air to enter the chest, and the expiration, which is still more painful and three or four times as long as the inspiration, does not drive out the inspired air. . . . We do not see sucking-in, as in croup, because in asthma the chest is always filled to its maximum with air."

In the true variety the nervous element is alone in play and it is only when catarrh appears that the picture is modified. "The attack of asthma is certainly produced by spasm of the muscles of respiration," though authorities disagree in allocating the spasm to the intrinsic muscles of respiration, the extrinsic, or both. Asthma is a neurosis and presents all the caprices of such, and further, it is almost always a diathetic and hereditary neurosis.

"The spasm of the respiratory muscles and the phenomena of vaso-dilatation and vaso-secretion are themselves due to a special condition of the nerves which govern these functions. This state of irritability is sometimes spontaneous or at least apparently so; at other times it is due to a reflex act which starts in the terminals of the sensory nerves which supply the bronchi or the nasal passages."

Thus Dienlaffoy, and if one reviews his treatment the drugs used are all those which have an inhibitory action on the vagus.

Now in coming to a logical conclusion as to what is the root mischief at work, wherein has lain our difficulty? As I regard it, the reason is that we have to deal with a condition which apparently is subject to no fixed laws, whether of heredity or environment; germinal origin, seasonal incidence, race, or age period. I say "apparently" is evidence, if we seek it, of some hereditary influence, of some relation to the age of the individual and to his environment. Thus, faced with the initial difficulty of incidence, can we isolate any one condition common to all cases, any one condition subject to the above influences, any one condition of which we could say: "This is the fundamental principle lacking in the human economy of all asthmatics, and this is the cause of asthma, however it as a cause may be produced"? I think we can do so.

The fundamental fault in the incidence of asthma I believe to be *suprarenal inadequacy*, and I propose to advance as briefly as possible evidence in favour of this opinion.

Some months ago the one question knocking at my brain was: Why do so many cases of asthma obtain such marked and definite relief—even though only of a temporary nature—from an injection of adrenaline or some such derivative of the suprarenal medulla? The answer was: This supplies the suprarenal medulla; this has to do with the cause of temporarily a deficiency; this has to do with the cause of the condition, and is a manifestation of the specific action of adrenaline in restoring the normal tonus of the bronchial muscles.

On this basis the problem required much wider, more minute, consideration: the first principle involved was the review of the known action of the extract of the suprarenal glands, and the second was how this action could be affected or modified by external influences acting on the glands or by influences on the glands themselves. The actions are familiar, but they will bear recapitulation.

The glands probably have two secretions—one produced by the medulla and one from the cortex—whose action may be supplementary, but probably is antagonistic, to adrenaline. We owe to Langley the discovery that the action of adrenaline on any part . . . of the sympathetic nerves is on a structure that at no time in its history has been innervated by the sympathetic. Elliott, in extending these observations, has brought forward some facts which suggest that, after excision of the suprarenals, the muscles innervated by the sympathetic cannot be thrown into activity even by electrical stimulation of the nerves.

Adrenaline appears, then, to be a chemical body whose presence is essential to the activity of the sympathetic. Nor is this the only example of such an association, for sympathetic paraganglia and structures such as the carotid body contain paraganglia—a similar but more stable body which does not lose its effect even if . . . with the stomach wall for twenty-four hours.

It has little or no action on the vessels of the heart itself. It has little or no action on the vessels of the lungs or brain. It liberates sugar in the blood. It causes relaxation of intestinal muscles and of bronchial muscles. It contracts all sphincters. It can bring about rapid recovery of the normal irritability of muscle after this has been lessened by fatigue, and this is an inherent property of adrenaline itself and not produced through its influence on the circulation. The glands are innervated by the sympathetic system, and since the secretion stimulates the same activities that are stimulated nervously by this division, it is possible that disturbances in the realm of the sympathetic, although initiated by nervous discharge, are automatically augmented and prolonged through chemical effects of the adrenaline solution.

Every one of the visceral changes noted—the cessation of processes in the alimentary canal (thus freeing the energy supplied to other parts), the shifting of the blood from the abdominal organs and skin to the organs mostly in need of them, the lungs, heart,

\* Abstract of a paper entitled "Asthma—a phantasy with some facts," read before the Durban Medical Society.

and central nervous system; the increased vigour of contraction of the heart, the quick abolition of muscular fatigue; the mobilizing of energy-giving sugar into the circulation—every one of these visceral changes is directly serviceable in making the organism more effective in the violent display of energy which fear or rage or pain may involve (Cannon). Thus the emotions affect the glands and the adequate response is made.

My next remarks may seem irrelevant, but I wish to show how the glands may be affected by simple causes, and thus lay the foundation for assuming that some such cause may be at work in the production of asthma.

Why does a red rag irritate a bull? The retina in its pigmentation and because of its pigment must be in close association with the suprarenals. Certain retinal cells and fibres are connected through the autonomic system with the adrenal medulla; certain cells are connected through the same system with the adrenal cortex; and therefore, as the retina in different animals, races, and individuals differs in its structure and sensitiveness, so in the bull the connexion with the adrenals may be such that red as a colour immediately stimulates and rouses it and the associated glands, with the resulting increased production of adrenaline and the stirring up of pugnacity and the emotion of anger.

We know the stimulant effect of red as a colour—a stimulation which goes on to irritation if one is too long exposed to it. Red stimulates the suprarenal glands to overproduction of adrenaline, with consequent demonstrable influence on the emotions. Black and darkness depress and frighten, and asthma in most cases is of nocturnal occurrence. The inference, as related to adrenaline production, is obvious. Assuming, therefore, an origin for asthma arising through the medium of the retina, can we not with equal justice assume that an influence in the nose, acting through the sympathetic, can produce suppression of adrenal secretion, with resultant asthma, or border-line asthma precipitated by the added depressing influence of darkness? The vital tide is at its ebb at 2 o'clock in the morning.

Can we not proceed on the same lines, and assume that indigestion or a heavy meal (and remember the stomach and bowel congestion, the lethargy produced by the necessity of digestion is the antithesis of what obtains when there is a superabundance of adrenaline in the blood) may reflexly affect the suprarenals with temporary suppression of secretion, permitting the onset of an attack of asthma? Once got a suppression of sufficient magnitude and in most cases an attack supervenes.

Assuming that this theory of adrenal suppression, as the cause of asthma, is correct, let us briefly consider the mechanism at work.

The bronchi, or rather bronchioli, affected are directly innervated by the autonomous nervous system, and this innervation is through the medium of two distinct entities, the sympathetic nervous system and the vagus. The sympathetic, as concerned in the mechanism of asthma, keeps the bronchioles patent. It is definitely stimulated to activity by adrenaline. Further, it is closely interrelated with the adrenal glands and conveys to them stimuli which increase their activity, and, what is even more important in the present discussion, impulses which may suppress function. The vagus action is directly opposed to that of the sympathetic and it is the careful balance of these opponents which maintains bronchiole equilibrium. Unopposed by the sympathetic, the vagus produces spasm of the bronchioles and consequent asthma.

Again, during sleep the endocrine glands are at rest. The sympathetic, receiving no external impressions, unstimulated by internal secretions or relatively so, is sleeping as well, while the vagus—concerned in the perpetuation of cardiac action and rhythm, bowel peristalsis, respiration, etc.—is necessarily active. We can, therefore, all the more readily appreciate the propensity for asthmatical attacks to develop during sleep. And so it is in practice—asthma, colic, and labour pains tend to develop while the sympathetic is at rest.

Thus, given bronchiolar muscle of border-line instability, it may be kept apparently stable by an active sympathetic. The activity of the sympathetic depends on a steady flow of adrenaline. This may be just sufficient during the day when the sympathetic is wakeful and continuously requesting the glands to function. But when the sympathetic sleeps, what then? The supply of adrenaline is more or less rapidly exhausted, the gland sleeps with the sympathetic; and calls for more secretion are not made and not received. Asthma supervenes.

In leading up to this I have endeavoured to indicate a selective action of suprarenal products, as of all endocrine products. But why should one person get asthma and another, under apparently identical conditions, not get it? It is all a question of degree. The normal individual manufactures normal amounts of internal secretion, enough to

keep the peace during the day and to tide him through the hours of darkness. But glands vary as do individuals. If the thyroid can be deficient in one individual, then why not the suprarenal in another? Thus we assume congenital deficiency. Again, it is known that glandular function may alter without any definite evidence in the glands themselves. If this can happen with the ovary, thyroid, and pituitary, why not with the suprarenal? Thus we assume deficiency later in life. Moreover, glands are subject to disease processes and toxic influences, and adrenal hypofunction and asthma may often be a sequel of some other exhausting disease.

But there are cases of asthma which we can explain by none of these suppositions. Endocrinologists inform us, and produce indubitable proof, that the endocrine glands form a chain, the strength of which depends on the integrity of each link. Let one link of the chain be malformed, weak, distorted, or broken, and the chain as such gives evidence of the weakness when put to the strain; and, moreover, the weakness is found at the particular link affected. Exophthalmic goitre, cretinism, Addison's disease, dystrophia adiposa genitalis, acromegaly, osteomalacia, are all cases in point. But the chain means more than that: the perfection of action of one gland link depends on the perfection of action of another gland link.

Thus the ovary and thyroid are interdependent, as are the thymus and ovary, and change in one is evidenced as well in the other. Now the ovary has a close relation with the suprarenal, and so has the thyroid. During pregnancy the action of the ovary in certain directions is in abeyance. Menstruation has ceased. That there is in many cases some deleterious effect produced on the suprarenal glands is certain. They are the chromophil glands, and we have only to note phenomena of brown areolar pigmentation, brown discoloration of the skin, apathy, somnolence, all indicating a kind of pseudo-Addison's disease. To what does this lead us? To the supposition that the ovary has a stimulating influence on the suprarenal glands. Before puberty this stimulation is absent; it is absent during pregnancy; it is lost after the menopause.

Is not asthma a condition rather of ante-puberty or post-menopausal ages? Have we not all made brilliant prophecies concerning the disappearance of the child's asthma at puberty? We were taught so by experience, but we did not understand the mechanism at work. May we not attribute the emotional disturbances of the climacterium with its flushings, etc., to a disturbed and constantly changing function of the suprarenal glands?

So much for the ovaries. Similar evidence can be adduced showing that inhibition of function or excess function of other glands may produce a suppression of suprarenal function. The adenoid and lymphoid overgrowth one associates with the youthful asthmatic is the direct result of glandular abnormality. Thus we adduce faults in the glandular chain which may work towards adrenal deficiency and consequent asthma.

Throughout this paper I have argued that asthma is primarily due to suprarenal inadequacy. In the present state of our knowledge of the separate actions and concerted interrelation of the endocrine glands it is difficult to substantiate this theory by facts which have the confirmation of physiological and pathological proof. It may, indeed, be necessary to enlarge the scope of the theory, and to accept a disorganization of the endocrine chain as a whole as the fundamental reason for this distressing condition. Nevertheless, on the supposition that suprarenal inadequacy is the chief factor in the incidence of asthma, the problem of treatment becomes somewhat simplified.

We must have two objects before us in undertaking treatment:

(1) It is necessary to discover the adverse influence at work, be it in the eyes, nose, throat, abdominal tract (and, of poisons there, I include peptone products), thoracic tract, or urinary system, or be it in the associated endocrine glands. We must try to discover it and eliminate it, calling to our aid all the devices that medicine and surgery have bestowed on us.

(2) We must reinforce the action of the suprarenal glands themselves, and re-establish normal function.

I defer consideration of (1). Each case must be dealt with on its merits and the origin located; appropriate treatment must be instituted to deal with it, bearing in mind that failure to do so may prejudice or stultify the results of treatment instituted under (2). For treatment under (2) we have at our disposal

the extract of the suprarenal medulla itself, and we have the extracts of glands known to work in unison with it. It is my practice to order mixed gland because I can see no harm in giving an overdose of a gland substance known to stimulate the suprarenal glands, and no harm in giving gland substance which has no demonstrable action on the suprarenal. But where there is evidence of hyperfunction of any particular gland I withhold that gland substance in treatment.

It will be said: "But we have all had failures with the exhibition of adrenaline in asthma." Perhaps these can be explained by reference to the properties of the extract and to what happens when it is administered. When given subcutaneously it brings about intense constriction of subcutaneous vessels and thus tends to defeat its own absorption. It does the same in the stomach, but this may not be a disadvantage. It is rendered inert though not destroyed in an alkaline medium. The stomach contents are acid and the vaso constriction produced would be useful in producing a slow, continuous absorption, unlike the quick absorption obtained from an intramuscular injection, for adrenaline dilates intramuscular vessels. Therefore, for immediate ease, an intramuscular injection should be given; and oral administration employed for a slow continuous action.

My great difficulty in compiling this paper has been the paucity of available bibliographic references to the endocrine glands and asthma. There are, I feel, many flaws in my argument, but if the paper serves to stimulate discussion I shall feel amply rewarded.

## THYROIDISSURE FOR MALIGNANT DISEASE IN A MAN OF 74.

BY

W. J. HARRISON, M.B., M.R.C.S.,

BERKHOE, EAR, NOSE AND THROAT HOSPITAL, NEWCASTLE-ON-TYNE.

The case here reported is interesting in view of the advanced age of the patient. So far as I have been able to ascertain, the only instance in which thyroidissure has been performed on a patient older than this is that of a man aged 75, on whom Sir StClair Thomson operated successfully. There is naturally a certain amount of hesitation in advising an operation on a patient of such an age, especially if he is at all debilitated, but this man is more vigorous than usual at this time of life—thin, but with good arteries, and unhesitatingly chose to have the operation.

W. T., aged 74, attended as an out-patient at the Throat Hospital in May, 1922. He complained of hoarseness of several months' duration, and this was the only symptom. A small warty growth could be seen on the margin of the right vocal cord, at the junction of the middle and anterior thirds. There was no lagging of the movement of the cord, the only impairment of the movement being caused by the mechanical obstruction of the growth to proper apposition. A specimen showed the growth to be a squamous-cell carcinoma.

On June 6th thyroidissure was performed. The isthmus of the thyroid gland was ligatured and divided and tracheotomy performed in the median position. Before opening the trachea a 2 per cent. solution of cocaine was injected into its lumen and into the interior of the larynx. The tracheotomy tube was inserted and the larynx opened without any of the usual disturbance. On exposing the growth by sawing through the ossified thyroid cartilage it was found that, as is so often the case, it was much more extensive than it appeared to be, spreading below the cords across the anterior commissure to implicate the tissue below the opposite cord in the anterior part. In consequence a considerable amount of tissue on both sides of the larynx had to be removed; this was done after placing a swab dipped in 2 per cent. cocaine into the larynx and packing off the trachea and pharynx.

As soon as he recovered consciousness and there was no sign of bleeding the tracheotomy tube was removed, a suture having been placed in each side of the trachea at the time of the tracheotomy. These were left *in situ* for a short time, so that if necessary the wound could be readily opened and the tracheotomy tube reinserted. He was kept in the upright position in bed and encouraged to get up and sit in a chair from the third day onwards; convalescence was uneventful. A small tumour appeared at the anterior commissure and persisted for several months; this was removed and proved to be the remains of granulation tissue with no evidence of malignancy. He now speaks in a loud whisper, which, taking into account the amount of tissue which had to be removed, is as much as can be expected.

The case illustrates clearly the importance which should be attached to persistent hoarseness or alteration of voice occurring in a man over 40. Semon and all laryngologists have pointed out the great importance of a laryngeal examination when it occurs, but unfortunately this symptom is

frequently ignored until some other reason sends the patient for an examination. Then it is too often found that the disease has progressed to such an extent that operation is impossible, and only a very severe operation offers any prospect of success. Alteration of the voice, being the only symptom of intrinsic cancer for some considerable time, should arouse suspicion when occurring in a man of 40 or over, which suspicion should not be set at rest even if no growth is visible at the time of examination, unless some other definite cause can be found for the condition, treated and cured. It is now possible to examine the larynx below the vocal cords by means of a mirror, introduced by Irwin Moore, so early growths in this region can be detected. As in the case mentioned above, the growth is frequently more extensive below the cord than is at first imagined. Impaired mobility or lagging of the cord implies some infiltration of the intrinsic muscles by the growth, and when present in conjunction with a growth is considered pathognomonic of malignant disease. In the case recorded it was not present; in spite of the size of the growth. In the larynx, as in other situations, epitheliomatous growths may be divided into those which tend to grow outwards (exfoliate) and at first show little tendency to invade the deep tissues; those which at first tend to extend over the surface, with little tendency to exfoliate or invade the deeper tissues; and those which tend to invade the deeper tissues at an early period of their growth.

The injection of cocaine into the trachea and larynx is of great value in the operation. Everybody knows the violent coughing, venous congestion, wide movement of the trachea, etc., which occur as soon as it is opened. After introducing a few drops of the 2 per cent. cocaine solution it can be opened with absolutely no disturbance. The disturbance when opening the larynx is even more marked, and the manipulation of the tissue may, by the inhibitory action of the branches of the recurrent laryngeal nerve, cause dangerous and fatal collapse. All this is done away with by the use of cocaine, which has the still further advantage of greatly reducing the haemorrhage and more clearly defining the growth and diminishing the shock.

The early removal of the tracheotomy tube is a matter of considerable importance, as it enables the patient to cough up secretions much more easily than when the tube is retained. It can easily be replaced, by the nurse if necessary, if sutures have been placed in the trachea, the wound being easily opened by traction on them.

The median position of the tracheotomy opening offers several advantages. After division of the thyroid isthmus the trachea is superficial in this region, so the operation is more easy than low tracheotomy; the tube can readily be reinserted if necessary, and during the operation is sufficiently out of the way not to cause inconvenience. In high tracheotomy the tube is in the way during the operation, and the thyroid isthmus, which has to be retracted when the trachea is opened, may get in the way and cause difficulty and delay in replacing the tube should necessity arise after its removal. In low tracheotomy there is often much difficulty in reinserting the tube owing to the depth at which the trachea lies.

## PRIMARY UNION AFTER OPERATION FOR SUPPURATIVE APPENDICITIS.

BY

ROBERT G. RIDDELL, M.D., F.R.C.S.E.,

HONORARY SURGEON, ROTHERHAM HOSPITAL.

It is now the practice of many surgeons to close the peritoneum without drainage in cases of abdominal sepsis, such as perforated gastric or duodenal ulcer, pyosalpinx, and appendicitis with localized abscess or general peritonitis, when it has been possible to remove the focus of infection. In such conditions, the root of the trouble having been removed, and as much as possible of the septic material having been swabbed out, the peritoneum is left to deal with what remains; provided that the infecting organism does not belong to one of the more virulent strains of streptococci (when the patient has not been left till in extremis, and provided also that the patient has not been reposed in it, that membrane seldom betrays the trust reposed in it.

The tissues of the abdominal wall have not the same

capability as the peritoneum of dealing with infective organisms, and as it is almost impossible to prevent contamination of the parietes during the operation for the removal of the septic focus, it usually happens that the wound suppurates and breaks down. Healing is then a very slow process, and a weak scar is likely to result.

*Bacillus coli* is the usual offender in appendicitis, and signs of mischief do not manifest themselves before the fifth day, when a little local discomfort and a slight rise of temperature give an indication of what is happening. Sometimes there is no evidence of trouble when the clips are taken out on the fifth day; and it may not be till the tenth day, when the supporting stitches are removed, that the edges of the wound fall apart, and a thin offensive pus appears. It is not difficult to clean such a wound; eusol or flavine will make it look quite healthy in a few days, but the slow process of granulation is a serious matter both for the patient and for the hospital. Secondary suture hastens matters in some cases, but is not always successful, and sometimes not advisable. The complete breakdown of the wound may, to some extent, be avoided by inserting at each end a drain reaching down to the fascia. These should not be removed earlier than the fifth day.

It is worth while, however, to attempt more than this, and to endeavour to obtain primary union, first by protecting the wound as well as possible against infection, and secondly, if that fails, as in most cases it will to some extent, to try to destroy the contaminating organisms. Where purulent fluid wells up immediately on opening the wound there is little chance of keeping the wound clean; but in cases of localized abscess it is possible to protect the edges with tetra cloths stitched to the peritoneum, or with the rubber-backed cloths recommended by Bonney, held in place by his special clips. If the abscess is small, the pus may then be mopped out without soiling the wound. Even then it is a difficult matter to keep the protecting cloths in position during the manipulations necessary in performing the operation, and one can never be quite certain that infection has not taken place. It is advisable, therefore, in all cases to disinfect the wound after the peritoneum has been sewn up; and it was in order to find a suitable antiseptic that various chemical agents were tried in the small series of cases tabulated below. The cases were all emergency ones of acute suppurative appendicitis, five having localized abscess and seven having general peritonitis. In all of them the appendix was removed, pus and fluid mopped out as well as possible with dry gauze, and the peritoneum and abdominal wound firmly sewn up. All did well eventually, though with varying success as regards union of the parietal wound, as will be seen.

Eusol was tried first, but appeared to have no effect. *Violet green* seemed to have an inhibitive effect on microbic growth, and delayed the appearance of sepsis till the tenth day, when the whole wound broke down (No. 4). *Iodine* produced a first intention wound in one instance, and only slight failure in another. *Flavine*, 1 in 1,000, gave the best results. It was used in the last seven cases and all healed by primary union except one, where the tissues were soaked with purulent fluid as soon as the peritoneum was opened, and where the operation was long and the patient weak (No. 8). *Bipp* was not used in this series. I have tried it in other similar conditions, with unfavourable results.

Flavine should be very thoroughly swabbed into every corner of the wound, which should then be flooded with it, and afterwards gently dried out. It is not advisable to run saline into the abdomen, either to wash out the peritoneum or for absorption. In the former case the wound will become hopelessly saturated, and in the latter there is likely to be leakage through the peritoneal suture, with consequent infection of the parietes, especially as the patient has to assume the Fowler position. Saline should of course be given freely by the rectum for the first twenty-four hours.

## OSTEITIS OF THE TEMPORAL BONE WITH MENINGITIS.

BY

H. LAWSON WHALE, M.D., F.R.C.S.,

OTO-LARYNGOLOGIST TO THE HAMPSHIRE GENERAL HOSPITAL, AND TO THE LONDON TEMPERANCE HOSPITAL.

The following case is of interest on account of its complicated nature, for, in addition to osteitis of the temporal bone and meningitis, extradural abscess and lateral sinus thrombosis were also present. The satisfactory result would appear to be due largely to the use of bipp.

Florence G., aged 11, was admitted under Dr. Porter Parkinson to the London Temperance Hospital on November 10th, 1922. For the previous week she had complained of earache (right), but latterly rather of general headache and pain behind the eyes. On November 5th there had been a slight discharge from the right ear. On and after November 7th she had vomited daily. Since November 9th her arms and legs had twitched occasionally. On admission the temperature was 103°, pulse 114, respirations 20. The child was drowsy and complained of pain behind the eyes. There were no physical signs of disease in chest or abdomen. Edges of both optic discs indefinite and "fuzzy." Veins dilated. Otherwise cranial nerves normal; no facial paresis; no demonstrable deafness. There was some rigidity of neck. Kernig's sign and tache cérébrale present. The knee-jerks were normal, as also was the flexor plantar response on both sides. There was a slight inoffensive watery discharge from a small central perforation in the membrana tympani of the right ear and tenderness over the mastoid, chiefly at the tip; no oedema. There was no thickening in the neck over the jugular. Dr. Porter Parkinson agreed with me that there were no physical signs to warrant operation.

November 11th: Lumbar puncture: cerebro-spinal fluid under pressure and turbid. Pathologist's report (Dr. Sanguinetti): Many polymorphonuclear pus cells, but no organisms seen. Culture sterile.

November 17th: The patient was less drowsy. The temperature had fallen on November 15th to 98.3°, which had been the average temperature ever since. Tenderness over right mastoid, and slight puffiness behind angle of right jaw. Head rigidity and tache cérébrale still present. No paralysis, anaesthesia, or other focal signs.

November 21st: The temperature shot up to 104° without rigor or convulsion. Obvious puffiness over the right mastoid. Optic neuritis on both sides, more marked on the right. The right pupil was larger than the left. At 6 a.m. the temperature was 104°, pulse 128, respirations 28. It was decided that operation must be deferred no longer; and the patient was transferred to my care by Dr. Porter Parkinson.

### Operation.

The operation was done under general anaesthesia (Dr. Hirsch). Preliminary lumbar puncture yielded findings similar to those of November 11th. The antrum was now opened, but neither pus nor necrotic cells were found. On exposing the sigmoid sinus an extradural abscess was encountered overlying a black non-pulsating thrombosed sinus. Pus also exuded in small globules from the cut edge of the bone itself. Bone was freely cut away backwards, exposing the lateral sinus until healthy sinus wall was reached, and no pus exuded from the bone. The thrombosed sinus was sausage-shaped, two and a half inches long, and quite black and inelastic.

A pack of ribbon-gauze was placed between bone and dura behind to control bleeding, and the whole length of the thrombosed sinus slit open and clot evacuated. The wound was packed with gauze. The bony "bridge" was not touched. The dura (excepting the outer wall of the lateral sinus) was not opened to examine the brain. The internal jugular vein was not tied, the neck not being interfered with at all.

The patient endured these procedures fairly well. Immediately after operation the temperature fell to 99°.

### Subsequent Progress.

November 24th: The temperature has remained low—93° to 99.6°. Wound re-dressed with gauze soaked in bipp, under short general anaesthesia. The sinus bled, but only from about one-sixth of the length of the original incision.

November 29th: Wound re-dressed under general anaesthesia, cleaned with hydrogen peroxide, saline, and spirit, and repacked with bipp gauze. No bleeding from the sinus, which was almost completely covered by healthy granulation tissue. Lumbar

No.	Sex.	Age.	Lesion.	Anti-septic.	Result.	Days in Hospital.
1	M.	39	Perforated appendix, general peritonitis	Eusol	Infected, broke down	57
2	M.	32	Ditto	Iodine	Slight infection	23
3	M.	14	Localized abscess	Flavine	Slight infection	22
4	F.	63	Perforation, general peritonitis	Violet green	Infected, broke down	43
5	M.	18	Gangrene, general peritonitis	Iodine	Primary union	17
6	M.	17	Localized abscess	Flavine	Primary union	19
7	F.	12	Ditto	Flavine	Primary union	12
8	F.	34	Gangrene, general peritonitis	Flavine	Infected, broke down	58
9	F.	38	Extensive peritonitis	Flavine	Primary union	14
10	M.	8	Localized abscess	Flavine	Primary union	13
11	M.	25	General peritonitis	Flavine	Primary union	18
12	F.	63	Localized abscess	Flavine	Primary union	17

puncture: fluid under high pressure but clear. No organisms found. Culture sterile. Temperature for the past five days 97.8° to 99.6°. All drowsiness has disappeared; appetite and well-being are returning.

On December 4th the right pupil was still larger than the left and optic neuritis was more marked on the right side than before; there was right external strabismus (this was transient and will not be referred to again). On December 6th the wound was re-dressed as before under general anaesthesia. On lumbar puncture the fluid was normal in appearance and flow.

December 12th: Wound re-dressed under general anaesthesia. The temperature oscillated very slightly around normal. The patient sat up in bed. Optic neuritis, right and left, steadily diminishing. Swelling of discs: right, 2 D; left, 3 D. The oculist (Mr. Loosely) is of opinion that some degree of optic atrophy will result.

From this time onwards recovery was uneventful. The dressings since December 12th were performed without an anaesthetic. The membrana tympani had healed. With the Bárány noise-box applied to the left ear to exclude its function the right ear heard as follows: conversational voice, 20 feet; whisper, 4 feet.

#### Commentary.

1. Although on no occasion were organisms found in, or grown from, the cerebro-spinal fluid, the diagnosis of meningitis was nevertheless obvious from the turbidity and presence of pus cells.

2. In the course of the illness optic neuritis appeared early and disappeared late. Being a true inflammation and not a mere congestion, this lesion cleared up only slowly after the exciting cause had been dealt with.

3. The jugular vein was not tied. This was partly because the child would obviously not have stood the necessary prolongation of anaesthesia, but also because it is debatable whether the usefulness of thus cutting off the peripheral outflow (even although the common facial vein also be ligatured) may not be discounted by the remaining patency of the petrosal sinuses.

4. We have here another instance of the value of bipp. The intervals between the first four dressings were respectively 3, 5, 7, and 6 days; during the whole period the temperature remained low.

5. The residual hearing is very satisfactory.

### FATAL THROMBO-ARTERITIS OF THE RIGHT MIDDLE CEREBRAL ARTERY OF UNCERTAIN CAUSATION.

BY

F. PARKES WEBER, M.A., M.D., F.R.C.P.

THE following brief report of a case of fatal thrombo-arteritis of the right middle cerebral artery is of interest, and may serve to draw attention to a subject of some importance.

The patient, A. H., aged 43 years, a Russian Hebrew cabinet-maker in London, had a cerebral "stroke" of some kind on the evening of December 29th, 1922, and remained in a semi-conscious condition, with left hemiplegia, thought to be probably due to haemorrhage on the right side of the brain. He had previously enjoyed good health, and had had five children, all of whom were living. He was admitted to hospital on the morning of January 1st, 1923, still in a semi-conscious state. There was no fever. He could hardly be roused to answer questions. His left knee-jerk was greatly exaggerated. The plantar reflex on the left side was of the extensor type (Babinski's sign), and on the right side was of the normal flexor type. The cremasteric and superficial abdominal reflexes were absent on the left side and present on the right side. Ophthalmoscopic examination (Dr. R. Gruber) showed slight blurring of the inner margin of the optic discs, suggesting commencing optic neuritis. The brachial systolic blood pressure was 130 mm. Hg. The blood serum gave a completely negative Wassermann reaction. The urine was passed into the bed. The condition became gradually worse, and Cheyne-Stokes respiration preceded death on the evening of January 2nd.

#### Necropsy.

The necropsy, which was performed by the house-physician, Dr. G. Welsch, in my presence, except for passive congestion of the viscera, showed nothing special beyond thrombosis of the trunk and branches of the right middle cerebral artery, with extensive (white) softening on the right side of the brain. There was no chronic interstitial nephritis and the heart and great blood vessels were healthy. There was nothing to suggest cerebral embolism.

In regard to the microscopic examination I have to thank Dr. J. G. Greenfield for his kind help. There was evidence of arteritis, but not of syphilitic endarteritis obliterans. The main part of the middle cerebral artery (trunk) showed a degenerated inflammatory area on one side only. The inflammation appeared to be older there than in the more distal parts. At the region of the first branch of the middle cerebral artery the vessel walls showed similar inflammatory areas. As to the type of cells in the

inflammatory areas, many of the cells were so degenerated that it was impossible to be sure whether they were polymorphonuclear or not. Some of the less degenerate cells were definitely mononuclear and some were polymorphonuclear. By Gram staining Dr. Greenfield failed to find any definite organisms in the necrotic masses of cells or in their vicinity, though some were present in the clot. The arteritis was apparently confined to the main trunk of the middle cerebral artery.

Dr. Greenfield suggested that we might be dealing with an arteritis secondary to suppuration in the sphenoidal cells, which is often unaccompanied by obvious clinical symptoms. It has, however, occurred to me that the arteritis might have been analogous to the arteritis of middle-sized arteries in the extremities in so-called "Buerger's disease".

In a typical case of this disease, who had long had intermittent claudication of both lower extremities with absence of pulsation in the pedal arteries, I once was able to observe the commencement of thrombo-arteritis obliterans in the radial artery at one wrist. The man complained of a tender swelling in that situation, and when the swelling gradually subsided pulsation in that portion of the radial artery (which had been present up to the time of the appearance of the swelling) was found to be absent. This was several years ago, and pulsation has not returned. The process seemed to resemble what takes place in superficial veins during attacks of nodular thrombophlebitis, to which Hebrews with thrombo-arteritis of one or both lower extremities are sometimes subject. (That particular patient had suffered a good deal from superficial thrombophlebitis.)

It is worth mentioning that in the case of the patient A. H., some urine collected from the urinary bladder at the post-mortem examination was found to contain much albumin, but no tube casts. J. Sabrazès and Ch. Massias have recently (abstract in the *Presse médicale*, Paris, 1923, xxxi, p. 104) drawn attention to the occurrence of "massive" albuminuria, without tube casts in the urine, in cases of cerebral haemorrhage. They found that in a young rabbit, when 2 to 3 c.cm. of its own blood were injected into its brain, albuminuria accompanied the resulting apoplectic shock, the albumin in the urine reaching 4.6 per mille at the time of the animal's death, thirty hours afterwards.

### RUPTURE OF RENAL ARTERY AND VEIN BY SLIGHT INJURY: OPERATION: RECOVERY.

BY

E. MILES ATKINSON, M.B., F.R.C.S.,

CHIEF ASSISTANT TO A SURGICAL UNIT, ST. BARTHOLOMEW'S HOSPITAL;  
SURGICAL REGISTRAR, PRINCE OF WALES'S HOSPITAL, TOTTENHAM.

THE following case seems worthy of note as an example of the serious lesion which can occur in a hydronephrotic kidney as the result of very inconsiderable trauma. Moreover, I have not been able to find a record of any similar case.

A boy, aged 18, was admitted to the Prince of Wales's Hospital with haematuria. Two days previously he fell while playing cricket and pushed his elbow into his left side. The pain was very slight, and he thought so little of the accident that he continued playing. The next day his side was stiff and painful, and he was passing blood in his water all day. On the day of his admission the pain in his side was less, but he still had haematuria, and consequently consulted his doctor, who sent him to hospital the same afternoon.

On admission he did not look ill, distressed, or pale. The whole of the left side of the abdomen and the left flank were rigid and tender, sufficiently to make examination difficult; but palpation of the left kidney region revealed an indefinite swelling below the costal margin which was dull to percussion. The lower pole of the right kidney could be felt with ease. The abdomen was not distended and there was no evidence of free fluid. The temperature was 99°, pulse 104, and the urine contained old dark blood in large quantity. In view of the fact that the boy did not appear ill and that there was no fresh blood in the urine it was decided to do nothing in the way of operation, but to keep him quiet in bed. He continued to pass dark blood in the water for the remainder of the day, but with no rise of pulse rate. His bowels not having been open since the accident he was given an enema, with no result.

The following morning he seemed quite well, though still passing blood. There was no result from an enema. In the afternoon he suddenly vomited three times, and the pulse rate rose from 100 to 120. The abdomen was then seen by me later and when seen by me later was less rigid than before. He looked ill, and a large mass could be felt on the left side and in the flank, and extending down from the left kidney region to the iliac crest and extending down from the left kidney region to the iliac crest, dull on percussion. The abdomen was somewhat distended, tympanitic on the right side, with no evidence of free fluid. The

right kidney was now not palpable on account of the distension. The temperature was  $101^{\circ}$ , the pulse 126, the urine still contained much dark but no recent blood. Per rectum there was a little fullness in the recto-vesical pouch, but no tenderness. The rectum was empty. Having regard to the onset of abdominal signs, it was thought possible that at the time of the accident there had been a tear of the peritoneum, that since then there had been a gradual leak of urine into the peritoneal cavity, and that now a spreading peritonitis was beginning. I therefore decided to open the abdomen.

#### Operation.

The abdomen was opened by a left paramedian incision. The descending colon was found pushed forward by a large retro-peritoneal haematoma extending from the region of the left kidney down to the brim of the pelvis. This piece of intestine was small and contracted, but proximal to it the whole intestinal tract was definitely distended. There was no peritonitis. Apparently the large haematoma had so interfered with the action of the descending colon as to paralyse it temporarily and cause an intestinal obstruction which enemata had failed to relieve. It was decided to explore the kidney and at the same time clear out the haematoma and relieve the descending colon, and to do this from the loin in order to avoid contaminating the peritoneal cavity with a possibly infected haematoma. The abdominal wound was therefore closed and the kidney exposed from the loin. It was entirely concealed by organizing blood clot, which was cleared away until the surface of the kidney was reached. On clearing the organ further it was found to be a very large hydronephrosis in which practically no kidney tissue was left. As it could be of no functional value, and as a large right kidney had been palpated, nephrectomy was decided upon. The ureter was found with some difficulty, but the renal vessels could not be discovered. A mass of blood clot in about the position where the vessels should have been was ligatured, the kidney removed, as much as possible of the haematoma cleared out, and the wound closed with a small drainage tube in one angle. Vigorous treatment with calomel, pituitrin, and enemata soon reduced the distension and got the bowel working again, and the patient made an uninterrupted recovery.

#### Specimen.

An examination of the kidney removed showed a hydronephrosis due to a congenitally narrowed ureteric strait, the kidney substance being almost non-existent. On searching for the renal vessels they were found, not in the piece of tissue which had been ligatured, but torn off close to the kidney just below this. Both artery and vein were very much smaller than normal, as was to be expected in a congenital hydronephrosis, and both were occluded by a thrombus. The injury had apparently been sufficient to tear through both, and the resulting haemorrhage had ceased spontaneously. The vessels were certainly not torn through in removing the kidney, as shown by the large retrocolic haematoma and by the fact that both vessels were closed by a thrombus. Moreover, the blood clot in the region of the renal vessels was separated very carefully by blunt dissection in looking for them.

It is a well recognized fact that haemorrhage occurs from hydronephrotic kidneys on very slight provocation, but rupture of both renal vessels following such a trivial injury seems a matter of sufficient interest to put on record. Oddly enough, in connexion with this tendency of a hydronephrotic kidney to bleed, two days after the above patient's admission a man came to hospital complaining of a sudden onset of haematuria following a fall off a bicycle, in which he did not hurt himself at all. He was found to have a calculous hydronephrosis.

I have to thank Mr. Carson, under whose care the patient was admitted, for permission to publish this case.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### STRANGULATION OF AN APPENDIX EPIPOICA SIMULATING APPENDICITIS.

The following case is chiefly of interest in illustrating a mistake in diagnosis.

A young man gave me the history that he had just recovered from a second attack of "appendicitis." Four weeks had elapsed between the two attacks. On each occasion the onset was sudden; severe pain was felt in the right iliac fossa, accompanied by nausea and vomiting. For some weeks he had suffered from dyspepsia with much flatulence.

I found a tender spot about one and a half inches above and slightly internal to the anterior superior iliac spine. Deep pressure caused him to wince, and a small hard lump could be felt, closely resembling an inflamed vermiform appendix when encased by a roll of omentum. Abdominal rigidity was hardly perceptible.

Operation performed the day following my examination revealed a vermiform appendix evidently healthy. About three inches distal to the caecal extremity of the appendix, upon the postero-external aspect of the caecum, was exposed a small plum-coloured lump, sessile upon the peritoneal coat of the gut. The appendix and the small tumour were removed, and both were examined at the

Royal College of Physicians laboratory, Edinburgh. The report was as follows: "The appendix shows early follicular ulceration; the small tumour shows the structure of an appendix epiploica with inflammatory reaction and recent haemorrhage."

It is worthy of note that this appendix epiploica was found near the post-external taenia coli, and that it gave rise to a mistaken diagnosis of appendicitis.

GEORGE ROBERTSON, F.R.C.S. Edin.,

Honorary Surgeon, Dunfermline and West of Fife Hospital.

#### CONGENITAL ABSENCE OF THE RADIUS.

As cases of congenital absence of the radius are not infrequent, and therefore not mere curiosities, the report of the following cases may be of interest. Potel collected reports of 200 cases, and Antonelli found it twice as common in males in the 114 cases he collected. Kummel says the prognosis is grave, as the patients show a general lack of resistance to disease, 27 being the oldest age recorded. Tunny saw 11 cases in eighteen years. In 1882 Shattock described 4 cases in still-born foetuses; these were dissected and the specimens illustrated. His first case was identical with the two to be described. Milne, in 1915, recorded a case in an imbecile, but five fingers were present. Scord in 1915 described a similar case in which there was a strong syphilitic taint.

The first of the cases now to be recorded occurred on the left side in a male aged 18, admitted under Mr. Dobson for inguinal hernia. His family history is good and himself otherwise normal. The humerus is about 1 in. shorter than the healthy one; there is a great deficiency in muscular development. The elbow-joint is very limited in its movement. The carpus articulates with the outer border of the ulna, which is curved and shortened. This hand is usually pronated; almost full supination is possible with assistance. The scaphoid, trapezium, and thumb are absent. Syndactylism occurs in the second and third fingers, which cannot be fully extended. His first and fourth fingers are abducted. He grips firmly by flexing his wrist and fingers, especially the first, on his elbow. Movement up and down in the axis of the false joint is very free. In supination the wrist moves dorsally over the ulna.

FIG. 1.—Case 1: Congenital absence of radius.

FIG. 2.—Case 2: A, Congenital absence of radius. B, Thumb: absence of adductor pollicis and flexor brevis pollicis.

The second case occurred in a man, aged 30, with a good family history and himself quite normal otherwise. The shoulder muscles are well developed and the movements extraordinarily free. The arm muscles are functional but weak. The elbow moves freely through 90 degrees, beyond which it will not go. The forearm shows strong muscular bellies on the concavity of the ulna, which is very stoutly built. The hand shows absence of the thumb, scaphoid, and

trapezium. There are some irregularities and adhesions in the carpal bones and joints. The fingers show trophic changes in skin and joints, whilst the  $x$  rays show some sclerosis. Pronation and supination are possible with the aid of shoulder movements. On the opposite hand there is complete absence of the adductor pollicis and flexor brevis pollicis, otherwise the left side is normal. He says he lifts heavy weights better with his deformed arm, hooking the object between the hand and humerus, the shortness of the ulna permitting relatively small articles to be grasped.

The interest of these two cases lies in their occurrence in otherwise perfectly normal adults.

A. P. BERTWISTLE,  
Resident Surgical Officer, General  
Infirmary, Leeds.

## British Medical Association.

### CLINICAL AND SCIENTIFIC PROCEEDINGS.

#### ULSTER BRANCH.

The winter meeting of the Ulster Branch was held in the Medical Institute, Belfast, on January 25th, when Mr. ANDREW FULLERTON, C.B., C.M.G., President, occupied the chair.

#### Tetanus.

Mr. S. T. IRWIN read notes of three unusual cases of tetanus. The first of these occurred in a young man aged 18, who cut his right cheek whilst shaving, and shortly afterwards played a game of Rugby football. Two weeks later he developed an indurated swelling on the right side of the neck. This was incised but no pus was found; he was therefore given a prophylactic injection of antitetanic serum, although at this time there were no signs of tetanus. Four days later he complained of "cramps" in his abdomen, which was found on examination to be tonically contracted. On pinching the skin typical clonic spasms occurred. He was treated by massive injections of serum given hypodermically, intravenously, and intrathecally, which after twelve hours caused disappearance of the symptoms, and recovery was uninterrupted. The second case occurred in a farmer aged 50, who was suddenly seized with acute abdominal pain on the left side. Forty-eight hours later his abdomen was opened by a surgeon in the country. The pain reappeared on recovery from the anaesthetic. Twenty-four hours after the operation the left side of the abdomen was rigid with frequent attacks of spasmodic contractions. After treatment by antitetanic serum all symptoms had disappeared in fourteen days, but during this time the patient burst his abdominal wound on three occasions and eventually succumbed to a low form of general peritonitis. The diagnosis in the case was verified (1) by finding the *B. tetani* in the discharge from an old sinus leading to the femur above the knee, and (2) by extension of the convulsions to include—for a day or two—the muscles of the neck and jaw. The third case was in a boy aged 5 years, who received a scalp wound just above the forehead on the right side. It was sutured, but suppurated. On the fourth day the mother noticed an irregularity on the boy's face. On the eleventh day he showed right-sided facial paralysis, with inability to swallow fluids and great terror when these were presented to him—the so-called "hydrophobic symptoms" of this type of the disease. The involvement of muscles extended rapidly, accompanied by frequent attacks of clonic convulsions, in spite of treatment, and he died on the thirteenth day after receiving the description of cephalic tetanus given by Bruce and Golla in *Abnormal Forms of Tetanus*.

The PRESIDENT remarked that in the war there was little faith in the curative value of the serum in a well developed case of tetanus.

#### Cases and Specimens.

Mr. KIRK showed a rare abdominal tumour from a woman who had had a tumour for many years, but had always refused any surgical interference; suddenly acute symptoms developed, with vomiting, haematemesis, etc., and she eagerly submitted to an operation. A tumour was found, attached by a pedicle to the stomach; it had caused a dragging of the stomach, and induced the urgent gastric symptoms. Relief at once followed, and the patient made a quick recovery. The tumour was submitted to Professor Symmers, at Queen's

University, and sections under the microscope showed pancreatic tissue, one of which was demonstrated to the meeting. The fluid in it digested protein and starch. It was considered to be a developmental "bud" on the stomach, analogous to the "bud" on the duodenum, which developed into the pancreas.

Mr. IRWIN read short notes of two cases of dropped foot due to pressure on the external popliteal nerve. One was in a boy of 17; a small firm tumour of white hyaline cartilage was found in the neck of the fibula and pressed on the nerve. Mr. Irwin removed the piece of the fibula, and in six months the dropped foot had disappeared, and a skiagram showed no hiatus in the bone. The second case was that of a man aged 34, in whom a ganglion from the superior tibio-fibular joint grew down and penetrated the outer coat of the nerve; operation was successful. Mr. Irwin also read notes of a case of renal colic due to an abnormal renal artery, which was relieved by operation.

Dr. BOYD CAMPBELL showed a case of enlarged spleen in a man aged 48. In 1917, in France, the patient had a severe pain and swelling in the left side which lasted for nine months; it disappeared and recurred several times. In 1919 there was fluid in the peritoneal cavity, and the blood examination showed that the condition was not spleno-medullary leukaemia nor splenic anaemia; Wassermann examination gave a double positive result. The patient was put on energetic antisyphilitic treatment—courses of arsenic, mercury, and potassium iodide—and he improved rapidly; he had worked for two years, and his blood was now negative. The spleen was still to be felt, and there was a slight anaemia and leucopenia;  $x$  rays had been tried, without improvement.

The PRESIDENT read notes of a case of spontaneous reduction of intussusception in a male child aged 3 months. The typical sausage-shaped tumour was present, and the end of the intussusception was felt by the finger in the rectum; there was blood-stained discharge. A laparotomy showed the characteristic oedematous colon; the child got quite well after operation.

Mr. R. J. McCONNELL showed a case of cyst of the neck, and Dr. HALL showed a child with haemophilia and arthritic symptoms.

## Reports of Societies.

### PSYCHOTHERAPY.

A DISCUSSION on "Psychotherapeutics" took place at the meeting of the Medical Society of London, under the presidency of Lord DAWSON OF PENN, on February 12th.

Dr. E. FARQUHAR BUZZARD introduced the subject by pointing out that psychotherapy was as old as the practice of medicine itself. It had been the mainstay of medical practice for centuries, and no medical man had been consistently successful in treating patients who had not, consciously or unconsciously, applied its principles. That the method of psycho-analysis in unskilful or unscrupulous hands might lead to harmful results could not be doubted, but this was a charge which might equally be levelled against electrotherapy or vaccine therapy. If psychotherapy was to prosper and maintain its position the difficulties which beset its path must be frankly faced. Its success would depend ultimately upon the proper education of the public mind in respect to mental disorders, and education could not properly be undertaken until the medical profession itself was equipped for the purpose. There were inherent difficulties in the teaching of psychotherapy. It could not always be practised in the open, and the presence of students or graduates was sufficient in itself to abort any inquiry into a patient's mental condition. If a medical man was able to recognize mental as well as physical suffering, and to discriminate between those psychological ailments which he could alleviate and those which he must hand over to someone else, that was all that could be expected of him. Time was the essence of success in the treatment of a neurasthenic, but few doctors could spare it, and this brought in the question of the specialist. Much as the necessity for specialism might be deplored, it must be recognized that often only the skill and time of the specialist could provide any hope for the patient. The scope of psychotherapy in the case of organic disease was a field which must needs be cultivated by every practitioner of medicine if he was to avoid mortifying failures.

Psychotherapy depended for its success, not always on deep psychological learning, but only on an ability to understand human nature, combined with knowledge and experience of the natural history of disease.

Dr. WILLIAM BROWN took up a remark by Dr. Buzzard that diagnosis in psychopathology must precede treatment. Everybody would agree with that in principle, but in practice, unfortunately, the state of affairs was such that they could not make their diagnosis until they had started their treatment. One general method of treatment—analysis—was necessary both for treatment and for diagnosis, so that the almost paradoxical position arose in psychotherapy of cure preceding diagnosis. He would gladly agree that there should be a close correlation between theory and practice in psychotherapy and theory and practice in neurology; but seeing that the mental disturbances met with in border-line cases were admittedly correlated with changes in the cerebral cortex, this correlation could only be made use of if something were known about the cerebral cortex, and he believed that the physiology of the cerebral cortex was quite inadequate for the physiological explanation of these processes. For a long time to come psychotherapy would have to be dealt with independently of physiology; the gap between the two was at present unbridgeable. He believed that the study of war cases had made a great addition to the knowledge of psychoneuroses. The study had definitely proved, on the one hand, that Freud was right in attaching great importance to mental conflict and repression, but, on the other hand, that Freud was wrong in declaring that the fundamental cause was of a sexual nature. The war proved that fear was sufficient to cause psychoneurotic symptoms in a large number of cases. Another discovery of the war was the dissociated nature of hypnosis. The cases met with in the war were extremely easy to hypnotize; the more dissociated they were the more easy they were to hypnotize, and when encouraged to re-associate their minds they were less hypnotizable. Hypnosis was, therefore, dependent upon dissociation, and was a thing to be avoided.

Dr. S. A. K. WILSON thought that in many of the types of cases seen at hospital it was a waste of time to talk about any form of analysis. Often all that was necessary was to say, "I know all about your case; I know how to cure you." The removal of a single symptom sometimes started the necessary train in the patient's mind whereby he was able to work out his own salvation. Cases must now be tackled in a far more scientific manner than by the old "knock-down" methods (the bucket of water in hysteria, for example), but he sometimes felt that the pendulum had swung too far, and he got a little cynical and sceptical about certain results. It was desirable to keep a shrewd judgement in treatment, lest the subconscious be exaggerated at the expense of the conscious. Concurrently with this tremendous spate of articles and books on psychology, there was equal activity in the discovery of the earliest forms and signs of organic change in the nervous system, and it was well to keep an open mind as to whether a case which appeared to be clearly of a psychical nature might not be due to some obscure physical cause.

Dr. M. B. WRIGHT argued that there must always be different forms of psychotherapy. He himself saw more hope in psycho-analysis than in any other method. He believed that the best psychotherapy in the future would be done in nursery and schoolroom, where it properly belonged.

Dr. DAVID FORSYTH said that suggestion and hypnotism were brilliantly effective in selected cases, but both methods dealt only with symptoms, and not with underlying causes. Psycho-analysis, on the other hand, seemed to offer an approach to the solution of innumerable perplexing problems. Objection had been made to the importance which psycho-analysis assigned to the sexual life, but once it was admitted that the neuroses were disorders of the mind the result of repression, it might be expected that the commonest nervous maladies would be related to those feelings most commonly repressed in modern civilized life. Psycho-analysis was also important from the preventive point of view; the beginnings of neurotic trouble were due to causes really preventable.

Sir STCLAIR THOMSON mentioned the case of a young girl with well marked symptoms of hay fever. She referred to a habit of hers of pinching and rubbing her nose, and her father asked if he had any objection to treatment by a psycho-analyst; he said he had none, provided the psycho-analyst was a qualified man. In due course the medical psycho-analyst's report was sent to him. It declared that

the habit of pinching and rubbing the nose was a form of masturbation, and that this case seemed to fit in with the Freudian conception that woman, feeling the humility associated with her place in the world, connected this with the absence of the male genital organ, which the nose would seem here to have replaced. He would make no comment upon this amazing bit of analysis.

Dr. CRICHTON MILLER said that a great many psychotherapists were obsessed with only one possible etiology, and were continually missing points which they would not miss if they had had a longer clinical experience. Some of them also essayed to use any psychotherapeutic means when they could "only play on one string." The real place of analytical psychology, he maintained, was not in the clinic, but in the home and the school.

Dr. BARTON, Dr. CRIMP, and one or two others described particular cases within their experience.

Lord DAWSON summed up the discussion. They would all be ready, he said, to pay a tribute of admiration to Freud, who must not be held responsible for all the developments associated with his theory. Mind influences had always played a prominent part in clinical medicine, and must play a still more prominent part as civilization became more complex. Therefore he thought that medicine owed a great debt to the psychotherapists, though it was permissible to regret that so few of them had had a sufficiently wide clinical experience. Psychotherapists needed to take warning from many other specialties which had preceded their own and had suffered through a too exclusive emphasis. Psycho-analysis had a very proper sphere, but it carried certain disadvantages, among them the tendency to introspection which it was apt to provoke, and the undue prominence which it gave to the Ego. The experience of all physicians would be that sex questions carried with them extraordinary dangers. Sex seemed to feed upon itself in the most morbid way, and men who practised sex analysis sometimes became tainted with the very thing they saw in their patients. Sexual feeling should be kept healthy by the balance of other qualities in mind and body. He urged that mind treatment in the main should be linked up with body treatment. What analysis meant was an intuitive insight into the thoughts and feelings of the patient. Both mind and body contributed to the clinical picture, though he would not belittle the splendid work which still lay open to the specialist in the more difficult type of case.

### THE SCIENTIFIC BASIS FOR NON-SPECIFIC PROTEIN THERAPY.

At the meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine on February 13th, Dr. W. LANGDON BROWN presiding, a paper was read by Professor A. J. CLARK on "The scientific basis for non-specific protein therapy." The paper is printed in full at page 315.

In the discussion which followed the President said that for conditions of pernicious anaemia and other less definite blood diseases the method of transfusion had been used, and in cases yielding the best results a negative phase was established; there was a fall of corpuscles immediately after the injection, followed by a rise. The transfusion added some healthy ingredient to the blood and enabled the blood to improve. As Professor Clark had said, a washing out from the bone marrow occurred, and it was interesting to note the number of immature forms which were seen. In one case, that of a woman, aged 25, who had crippling arthritis, as no septic focus was discovered, recourse was had to non-specific protein therapy. After the fourth injection of T.A.B. she had a vaginal discharge and a swab was found to contain gonococci. It was a gonococcal arthritis.

Dr. H. H. DALE agreed with Professor Clark as to the probable action of non specific proteins in producing desensitization of the asthmatic patient. But the disappearance of the antibody effect or property seemed to be of too short a duration to account for the therapeutic effects. When blood was exposed to injury, or was brought into contact with a foreign body, causing such changes to occur as an alteration in the coagulation time, the blood seemed to acquire quite a potent toxic effect. The passing into solution of the platelets which occurred in these conditions was what would be expected.

Dr. A. G. ATLD said that he had adopted the method in the case of people who were very sensitive to ordinary peptone. One worker found that when he reprecipitated the

peptone in absolute alcohol several times the peptone quite lost its toxicity. The toxic substance in the proteoses was not histamine; it was a substance of which nothing was known, and which was only loosely attached to the molecule. Its physiological effect was similar to that of histamine, but the two were not identical.

#### *Treatment of Diabetes Insipidus by Intranasal Spraying of Pituitary Extract.*

Dr. H. BLUMGART, in a note on this subject, said that there was a group of cases of diabetes insipidus in which the cause could not be ascertained. In 1913 it was discovered that the introduction of extract of the posterior lobe of the pituitary body checked to a considerable degree both the polydipsia and the polyuria. But the effect was only transitory, as six hours after the treatment the patient was as bad as ever. Attempts had been made to introduce the extract by the rectum, and also by the mouth, but there was practically no effect from these methods in the hands of some, though a few workers claimed results from them. In one case he and his colleague found that 1/5000 c.cm. of pituitrin caused a drop in the urinary output and an alleviation of the thirst. He had experienced the best results from intranasal spraying with pituitrin. He used for this purpose Parke Davis's "Pituitrin O." The method had to be continued regularly, otherwise the case relapsed. In all the classes of cases benefited by the subcutaneous use of the drug it had proved efficacious when used intranasally. Dr. Blumgart's communication was in the main a summary of the work recorded by him in the *Archives of Internal Medicine* (April, 1922, p. 508), together with notes of three cases of diabetes insipidus which he had since observed.

Dr. H. H. DALE said that Dr. Blumgart's communication naturally raised the question whether the method could be applied generally—that is to say, whether there were other conditions presenting similar or even greater difficulties in requiring repeated hypodermic injections, and in which intranasal spraying would suffice. He desired to hear from Dr. Blumgart any remarks on the application of insulin by this method in America.

Dr. BLUMGART said that the point of absorption of the substance appeared to be high up in the nasopharynx, possibly through the cribriform plate. He had not experienced success in the use of insulin intranasally, but successes had been recorded in its intranasal use in large doses in rabbits. It had been found that in lead poisoning inhalation of the poison caused trouble in the upper respiratory passages, and the absorption of the lead in those passages was ten times what it was in the lungs themselves. There was an analogy between this condition and mode of entry and that of poliomyelitis, which was known to be by way of the nasopharynx rather than the blood stream.

### CONTROL OF VENEREAL DISEASE.

At a meeting of the Manchester Medical Society held on February 7th, with Sir WILLIAM MILLIGAN in the chair, a paper entitled "Public measures for the treatment of venereal diseases" was read by Colonel L. W. HARRISON.

He said that, as a result of the Royal Commission's recommendations, public authorities were asked by the Local Government Board, and later the Ministry of Health, to frame schemes for the treatment of venereal disease. The principle underlying the recommendation by the Royal Commission was to stop the spread of venereal disease by rendering the greatest possible number of the infected population non-infective. Conceivably a local authority, when required to frame a scheme for rendering the greatest possible number of the infected of its population non-infective, would think out:

1. All the kinds of people likely to be infected.
2. How to persuade these infected people to consent to treatment.
3. How to keep them under treatment until they had become permanently non-infective.
4. The provision of treatment centres.

The people likely to require attention were:

1. Those suffering from active diseases as a consequence of fairly recent sexual misconduct.
2. Those who had been infected in the past but believed themselves cured and were discovered only by reason of having communicated the disease to others, such as wives or children.
3. Those who had acquired gonorrhoea or syphilis innocently, such as wives of infected husbands and their children.

The innocently affected might require special provision for treatment owing to their probable objection to attendance at a venereal clinic, and Colonel Harrison strongly advised that this provision should be made at existing maternity and child welfare centres. The treatment of infected mothers had given most valuable results in the prevention of congenital syphilis, and no venereal disease scheme could be considered complete without the fullest provision for treatment of infected parents. It was not fair that a child should start life handicapped by inherited syphilis, and local authorities should ask themselves anxiously if they were carrying out completely the comparatively simple task of preventing it. Those who were discovered by reason of having infected others should be secured by a system under which wives were persuaded by social workers to send their infected husbands for treatment. Such a system was in operation at St. Thomas's Hospital, and many whole families had been brought under treatment by it.

As to the arrangements for the main body of the infected, Colonel Harrison pointed out the disadvantage of treating large numbers of venereal cases in premises ill adapted for the purpose, such as out-patient rooms of hospitals. It was economically unsound as it wasted man-power very seriously, and it led to defaulting on the part of the patients, since medical officers did not get a proper chance of treating their cases efficiently, especially in gonorrhoea, and the patients sooner became tired of attending. Experience had shown that premises specially designed for the purpose were necessary if the scheme was to be a success. In many cases voluntary hospitals had not made good provision for venereal treatment, and it would have been better in many cases to have established centres in separate premises. The theoretical objection to *ad hoc* clinics had not been substantiated by experience; they had proved to be just as successful as, if not more so than, the average clinic established in a voluntary hospital, and in future, if a voluntary hospital was not willing to give the facilities required for completely efficient work he would have no hesitation, in towns of any size, at any rate, in recommending the provision of *ad hoc* centres. With regard to the number of centres for a given size population, he thought that these should be few rather than many, since on the one hand transport was easy, and on the other a large centre was more economical than a small one. Clinics of any size should be open all day, say from 8 a.m. to 10 p.m., in order that patients might attend for intermediate treatment at hours convenient to themselves. Intermediate treatment was a daily business and likely to prove irksome in some cases; it was less so, naturally, if the patient could easily fit it in with his private engagements. It was a great advantage also if new cases could be seen at any hour, but the provision for this naturally depended on the size of the centre.

A number of slides of the venereal disease treatment centres at St. Thomas's Hospital and of the type plans of centres issued by the Ministry of Health were shown to illustrate the lecturer's ideas on the internal arrangements of treatment centres. The St. Thomas's Hospital centre had been in existence for nearly three years and was judged to be a success. The initial cost was high, but the running expenses were considerably lower than the average—in fact, the lecturer showed that the whole treatment required for the London area could be carried out in five such centres at a cost which was over £16,000 less than was at present being spent, though the London centres were not more expensive than those in the large provincial towns. With regard to the staffing arrangements, Colonel Harrison held strongly that each treatment centre should be under the control of one director, and he expressed his view of the great advantages which accrued to the public when the director of a centre was thoroughly imbued with the public health spirit. He pointed out that his work is to protect the community from venereal disease and that the treatment which he directs is to be regarded in the light of a means to that end. For the same reason he considered it most important that the closest sympathy should exist between the public health department and the directors of venereal disease treatment centres. At present those in charge of treatment centres were too closely shut up in watertight compartments, and regarded their patients rather from the individual than from the public health point of view. He reminded his hearers that this was a public health scheme, designed to render non-infective the greatest possible number of infected persons, and he considered that that end would

be served only by the determination of all concerned to allow no other consideration than its attainment to prevail in their councils on the subject.

### INSOMNIA.

At a meeting of the Edinburgh Medico-Chirurgical Society on February 7th, with the President, Sir R. W. PHILIP, in the chair, a discussion on insomnia was opened by Professor A. R. CUSNRY. He said that the nature of sleep was unknown; two theories had been offered—the first that sleep arose because of the action on the brain of toxic substances elaborated in the body, such as lactic acid or certain fatigue toxins; the second view was that the brain was not poisoned but exhausted, hence the great inducer of sleep was muscular exercise. Brain work itself was not a successful promoter of sleep, many forms of brain activity, such as worry, having the opposite effect. There were two types of sleep: the first and best was that in which the individual fell asleep a few minutes after going to bed, slumber gradually becoming more light as morning approached; in the second variety sleep for some hours after going to bed was light and fitful, and reached its greatest depth in the morning; this was the typical form of insomnia. As regards treatment, in the otherwise healthy person drugs should be employed only as a last resort. Among various general measures which, as a sufferer, the speaker had found helpful the following were mentioned: active exercise, which must not be excessive, and should be taken in the evening and in the fresh air rather than in a gymnasium; a cool bedroom and cool bedclothes; regulation of bodily functions; a peaceful book, read the last thing at night. The only drug he had used was bromide, which he had found ineffectual. Of the ordinary hypnotics chloral was probably best; its depressant action on the heart was negligible. The sulphonal group had the disadvantage of delayed action, and might be followed by serious symptoms coming on with little warning. Veronal was comparatively safe, but also slow in action. Paraldehyde, except for its objectionable taste and odour, was excellent. Alcohol had its place, in that it relieved worry. Where sleep was prevented by pain or motor excitement morphine or hyoscine was obviously indicated.

Dr. C. B. KER, speaking from experience of insomnia occurring in the febrile state, said that in such cases, as in other pathological conditions underlying insomnia, general measures had frequently to be supplemented by drugs. In insomnia due to fever cold sponging was often efficacious, and antipyretic drugs might be justifiable in reducing temperature so as to induce sleep. Bromide given in repeated doses from 6 p.m. onwards was occasionally helpful in placing the patient in a condition to get natural sleep. Morphine was excellent in the restlessness of diphtheria heart failure, as was hyoscine in the excited insomnia of cerebro-spinal meningitis. For ordinary purposes he was fond of chloral and bromide in repeated 10-grain doses; in the delirious insomnia of alcoholic erysipelas he found a combination of sulphonal given in the afternoon and paraldehyde some hours later successful. Bromidia was specially useful in children. Professor ROBERTSON said there were two types of insomnia: the first, in which the patient was restless till 2 or 3 a.m. and then fell asleep; the second, in which sleep came on at once, the patient waking easily. In the first variety a drug acting quickly, such as paraldehyde, was indicated; in the second a drug whose action was prolonged, such as veronal, was required. Veronal was therefore ideal in melancholia, where the tendency to suicide was greatest in the early morning hours. The combination of chloral and bromide was also useful. The speaker also referred to the value of suggestion in certain cases.

Professor MAKINS described three types of insomnia: first, the acute type, occasioned, for example, in acute fevers, and in such cases nursing methods, especially hydrotherapy, were called for, and drugs were sometimes necessary; second, the chronic form in which the cause must be found and dealt with, and drugs should be shunned—in this type suggestion was of value; third, the periodic variety, occurring in otherwise healthy people, after prolonged strain or heavy work—in these a holiday was all that was necessary.

Dr. TORRANCE THOMSON said that sleep was a response to a psychological necessity and referred to sleep from the psychological standpoint.

The President, Professor EDWIN BRAMWELL, Drs. KERRIE PATTERSON, SOMERVILLE, and JOHN ORR, also contributed to the discussion.

### RADIUM IN CANCER OF THE URETHRA.

The annual meeting of the North of England Obstetrical and Gynaecological Society was held in St. Mary's Hospital, Manchester, on January 19th. After the presentation of the secretary's and the treasurer's annual reports Professor W. BLAIR BELL was elected president for the ensuing year. The retiring president, Dr. H. CLIFFORD, gave his valedictory address on the history of abdominal surgery. This was received with great interest, and on its conclusion Dr. Clifford was accorded a hearty vote of thanks, both for his address and for his able services as president during the past year.

Dr. FLETCHER SHAW contributed two cases of carcinoma of the urethra treated by radium.

*Case 1.*—A maiden lady, aged 45, complained of great irritation of the vulva and painful micturition for four months previous to examination in November, 1919. A hard red growth extruded from the urethral orifice and extended for about half an inch along the lumen. There were no inguinal glands. As so many of the cases previously reported had incontinence after operation he decided to treat this case with radium, which was done in December, 1919. A year later there was some enlargement of the glands in both inguinal regions. These were removed, and a few of them showed carcinomatous deposits. She was seen at intervals, and there was no further recurrence till December, 1922—three years after the first treatment with radium—when a small inguinal gland the size of a pea, which had been overlooked at the first operation, was removed. This also contained carcinoma cells. There was no local recurrence in the urethra.

*Case 2.*—A married woman, aged 51, 3 para, complained of irritation of the vulva, dyspareunia, and slight haemorrhage for a few weeks. She had had a caruncle cauterized a few years previously. The growth was more advanced than in Case 1, and consisted of a hard, red, friable mass, the size of a sixpence, extending all round the urethral orifice, and the urethra was thickened and hard for about one inch. No glands were found. Treatment with radium in October, 1922; two months later the growth was very much diminished in size, though it had not disappeared. She would probably have another treatment in a month's time. It was much too early to form an opinion whether the condition would entirely disappear under radium treatment, and whether there would be a permanent cure.

The President (Professor Blair Bell) had seen an inoperable case, and also had had to deal with a fistula left after previous operation by another surgeon; in that case he had been fortunate in being able to mobilize the base of the bladder and remaining urethra and to bring them down to the vestibule with good functional result. Dr. DONALD suggested the combination of radium and surgery as the ideal treatment in this condition.

Dr. CHISHOLM said that fifteen months previously he had had a case involving the whole length of the urethra and the base of the bladder; he first did a permanent suprapubic cystostomy, as advised by McGill of Leeds, and then removed the urethral growth and base of the bladder. As it was doubtful whether the whole of the growth was removed, radium was inserted later. The inguinal glands were not invaded. Three months ago there was no recurrence; the patient was fairly comfortable and able to do a little housework.

Dr. FLETCHER SHAW, in reply, said it was very interesting to hear of so many new cases, as so few were to be found in the literature. The President's remarks were particularly interesting, as he had not thought it possible to regain control of the urine after complete excision of the urethra and base of the bladder.

Dr. LEITH MURRAY showed three specimens of strangulation: (1) of a normal appendage, (2) of a fimbrial cyst, and (3) of a broad ligament cyst.

Dr. D. DOUGAL showed two specimens: (1) of spontaneous separation of one ovary and adhesion to the floor of Douglas's pouch, and (2) of a six months' foetus with a teratomatous tumour growing from the sacral region. He suggested that these tumours might arise from the abnormal persistence of the "posterior growing point," and not be, as commonly considered, instances of conjoined twins.

Dr. LEITH MURRAY read notes of two cases of calcification.

1. Calcified ovary in a single woman, aged 31. Twelve months' amenorrhoea was followed by two months' continuous bleeding, six months' ... two months' continuous bleeding. ... areous ovary and rudimentary ... cured the patient. Chemically, the calcareous body consisted mainly of magnesium phosphate, with some calcium phosphate and traces of iron.

2. Calcified bodies in the uterine cavity associated with sarcoma of the ovary in a woman of 60. Three months' bleeding occurred fifteen years after the menopause; a mobile, cystic tumour reached nearly to the umbilicus; the uterus was enlarged and bore a cervical polyp. After removal of the polyp and diagnostic

curettage of the uterus, which appeared only to be enlarged, the abdomen was opened; the cyst, which presented the characteristics of a pseudo mucinous cystadenoma, was removed together with the enlarged corpus uteri. On opening the uterus, there were found lying loosely on the anterior wall seven flattened, glistening white, rosette-like bodies, 2.4 to 3.2 mm. diameter and 1.8 to 2 mm. thick; these seemed to have been dislodged by the curette without leaving any indication of their original site. Chemically, they consisted of calcium carbonate with traces of magnesium and iron. The ovarian tumour, on section, proved to be a short spindle-celled sarcoma. The patient was reported alive and well nine months later.

## ANATOMY AND PHYSIOLOGY.

A MEETING of the Section of Anatomy and Physiology of the Royal Academy of Medicine in Ireland was held at the Royal College of Surgeons in Ireland on February 9th, with the President (Mr. A. A. MCCONNELL) in the chair.

Professor E. J. EVATT showed a camera-microscope and a number of very clear embryological photographs which he had obtained with it. In making the camera and in the production of the photographs he was indebted to Dr. Henry and Mr. Nolan. He claimed for the camera great simplicity, stability, and small cost.

Professor Evatt then made a communication "On the growth of normal structures into adjacent tissues." In the growth of tissues, he said, the invaded tissue was always highly vascular, and the less vascular the tissue the less was it liable to be invaded by the ingrowing cells. The reaction of tissues to invading cells was accompanied by marked proliferation of the invaded cells. This proliferation was not so noticeable in the case of ectodermal as of endodermal cells. The line of separation between invading and invaded cells was marked by the basement membrane. In the growth of glands he did not find any basement membrane between the epithelial cells, nor did he find a basement membrane in relation to the bile capillaries. He considered that the commencement of the neural groove was due to a solution of the underlying cells.

In a discussion on the paper, Professor Scott found himself in disagreement with the author on several points, especially on the question of the basement membrane, which he considered did not exist. The communication was also discussed by Professors Dixon and Pringle and the President.

Professor H. PRINGLE described a curious difference in appearance that he had observed in the walls of large and small arteries respectively in cases of aneurysm. He found that in large arteries the elastic tissue of the wall was the first to disappear, whereas in the case of the small arteries it was the most resistant part of the wall. In large arteries the elastic coat could be traced as far as the wall of the aneurysmal sac and then it faded away. In small arteries the external elastic coat could be traced all round the wall of the sac. He demonstrated his findings with a series of very clear slides of aneurysms of the aorta, brachial, and radial arteries.

The communication was discussed by Professor Scott, Dr. O'FARRELL, and Professors Dixon and Evatt.

Dr. C. M. WEST showed a foetus exhibiting spina bifida and abnormalities of the central nervous and digestive systems, for which he was indebted to Dr. Solomons. The spina bifida was of an unusually large extent, involving almost the entire vertebral column. There was a fusion of certain of the thoracic vertebrae, and ribs. There was a condition of hydrocephalus and syringo-myelocoele, the brain being considerably altered in shape. The caecum and appendix occupied an unusual position in the abdomen. Dr. West discussed the causation of the various abnormalities found. The President and Professor Dixon spoke on the communication.

Dr. A. K. HENRY communicated "A note on the interpretation of sulci on certain bones." He selected the sacrum and first rib as bones on which were recognized certain grooves, which were ascribed to causes other than those to which they were really due. The so-called subclavian groove on the first rib he considered was more probably due to traction by the scalenus anterior and medius, so that the bone was depressed between the attachments of these two muscles. He instanced the case of a small mastoid process associated with atrophy of the sterno-mastoid muscle. He illustrated his remarks with specimens and lantern slides.

The paper was discussed by Professor Dixon, Dr. West, the President, and Professor Pringle.

## MIDLAND MEDICAL SOCIETY.

A MEETING of the Midland Medical Society was held in the Medical Institute, Birmingham, on January 31st, when the President, Dr. PURSLOW, took the chair, and about forty members were present.

Dr. STANLEY showed a patient with an intracranial lesion for diagnosis. The case was that of a middle-aged man, who had definite paralysis of the third, fourth, fifth, sixth, and seventh cranial nerves on the left side, with no signs of spasticity of the lower limbs. The cranial nerves on the right side were normal. Dr. Stanley believed that the man had a "surface" lesion on the left side of the mid-brain, but pointed out that it was difficult to conceive a lesion of this type which would spare the right third nerve. The Wassermann reaction was negative and radiographs did not help. Mr. BEATSON HIRD, speaking of the appearance of the left eye, which was ... and secondarily infected, said he had seen similar conditions resulting from tumours near the basic sphenoid. Dr. STANLEY BARNES agreed with Dr. Stanley that this lesion was a surface one, but he differed from Mr. Hird, who had said there was no proptosis of the eye. In Dr. Barnes's opinion the lesion extended backwards from the foramen lacerum anterius, and was probably either a tumour of the dura mater or a slow suppurative process beneath it.

Dr. RUSSELL showed a young woman who had oedema of the left foot and leg associated with albuminuria. The oedema was always worse in summer. He stated that some time ago he had seen another exactly similar case. Physical examination revealed nothing abnormal, but on screening the chest Dr. Black had drawn attention to a very definite sclerosis. Investigation of the albuminuria following various postures had led to the interesting conclusion that it was derived principally, if not entirely, from one kidney. Dr. RUSSELL had been completely unable to find any plausible explanation for this curious association of unilateral oedema with albuminuria until Professor Brash had suggested that it might depend on the presence of a subcardinal vein on one side, a rather unusual anatomical abnormality. Mr. NUTTALL suggested that the ureters should be catheterized, but Dr. RUSSELL thought this unjustifiable in the case of a perfectly healthy young woman.

Mr. G. P. MILLS showed a patient after excision of the upper end of the femur (the operation had been undertaken for dislocation of the hip-joint after septic arthritis). The surgical result was disappointing, inasmuch as the shaft of the bone had not remained in the acetabulum. The functional result, however, was excellent, as the patient got about comfortably, and could walk a considerable distance, whereas prior to the operation she had been crippled and had suffered excruciating pain.

Mr. MILLS showed two children after tendon transplantation. Mr. NAUGHTON DUNN, in congratulating Mr. Mills on his results, stated that tendon transplantation was usually successful providing that the fundamental principle underlying it was not neglected—namely, that a muscle used for replacing another should be one with which the latter was usually associated in function.

Mr. ADAMS showed specimens from a case of suprarenal tumour with metastasis in the skull. The tumour had been palpable before any metastasis had appeared in the skull. This, he stated, was very unusual, but in the course of a brief discussion Dr. DOUGLAS STANLEY and Dr. A. P. THOMSON stated that they had had similar cases. Mr. NUTTALL discussed the question of surgical intervention in those cases in which the abdominal tumour was palpable and there was no obvious metastasis.

## PSEUDO-HERMAPHRODITISM.

At the 703rd meeting of the Brighton and Sussex Medical-Chirurgical Society, Dr. D. W. LIVINGSTONE, Vice-President, being in the chair, Dr. RICHARDS and Mr. GEOFFREY BATE read notes of two cases of androgynoid pseudo-hermaphroditism.

Dr. RICHARDS said that his attention had been drawn to the cases and 18, and that his attention had been drawn to the cases by his having been called to the first on account of a painful and irreducible swelling in the groin. Inquiry and examination showed that although she was, to all outward appearances, a girl, she had never menstruated. Suspecting the nature of the case, he sent it to Mr. Bate at the County Hospital. The nature of the first case having been decided, he made inquiry as to the rest of the family and found that the younger girl had swellings in both groins and had a similar

history as to menstruation. A younger sister, aged 14, is now suspected of being in a similar condition.

Mr. BATE said that before operating on the first case he had made a careful examination. Externally the whole configuration of the body was feminine; the breasts were very fully developed; pubic hair was almost absent; the labia, clitoris, and hymen were normal but somewhat small. Careful examination of the vagina through a Kelly's speculum failed to reveal any cervix or sign of any cervical canal. The vagina ended about one and a half inches from the hymen in a rounded roof. Bimanual examination, though difficult owing to the small size of the orifice, failed to reveal any evidence of uterus, ovaries, or tubes, though there was a very slight median thickening of the vaginal vault in the middle line. The inguinal swelling, when removed, proved to consist of a rounded body with a thick fibrous coat, to which was attached a small cyst. This body when examined was found to be a testis, and was attached below by a firm gubernaculum to the pubes, and was continued upwards in a cord which passed upwards out of reach towards the kidney.

The second case was in every way similar, though swellings were present and removed from both groins. The elder girl was very distinctly feminine in her ways and was definitely pretty. The second girl, though apparently feminine, was less of the "pretty" type than her sister, and she presented the bilateral swellings, which proved to be even more definitely developed testes than in her "sister's" case.

Mr. Bate illustrated his notes by lantern slides showing the feminine characteristics of the patients and the histology of the testes removed.

Dr. H. M. GALT said that there could be no doubt whatever about the structures present. Although the development was to a certain extent of the infantile or immature type the typical testicular structures were all present. There was a well marked tunica albuginea, and in the more central portions of the sections the tubuli seminiferi were present in abundance and were quite characteristic, showing the convoluted structure of the tubes and the lining of the special columnar cells. From the appearances there was little doubt that the organs were functionally inactive, and that there was only a rudimentary fibrous mass representing the epididymis. There was also shown in one section what appeared to be a rudimentary vas deferens; this was in the form of a thick-walled muscular tube, but without any definite mucous membrane.

Mr. GEOFFREY BATE showed two cases of pseudo-coxalgia, one bilateral, and a case of traumatic epiphysitis of the hip for comparison. He read a paper on the former condition. After commenting on the inappropriateness of the name by which the disease was commonly known, he drew the attention of the Society to the importance of the condition being recognized, as its prognosis and treatment differed so materially from that of true hip disease. After giving an outline of the history of the condition, he quoted Platt's excellent description from the *British Journal of Surgery*. Having extended this somewhat, he showed a series of some thirty lantern slides illustrative of the condition, including radiograms of the cases shown and of other morbid conditions of the hip for comparison. He discussed the etiology and treatment of the condition, and emphasized the absolute necessity of radiographic evidence in diagnosis.

A MEETING of the Manchester Pathological Society was held on February 14th, with Professor J. SHAW DUNN, the President, in the chair, when Mr. PLATT showed various specimens and radiograms of "loose bodies in joints"; after giving a short account of the earlier work of Hunter and Brodie he discussed at length the relative merits of the more recent theories of "trauma" and "osteo-chondritis dissecans." Drs. ASHBY and SELLERS showed specimens from a case of chloroma occurring in a boy aged 12 years, who was admitted to hospital with swellings in both temporal fossae and orbital cavities of three weeks' duration. There was marked exophthalmos, headache, and lassitude, and the boy succumbed four weeks after the commencement of the illness. Dr. Sellers also showed specimens from a case of abdominal lymphosarcoma occurring in a boy aged 5 years. Interesting specimens of a myxoma of the appendix vermiformis and a large hydronephrosis resulting from a ureterocele were shown by Mr. JOHN MORLEY. Mr. MACALPINE demonstrated an unusual specimen of carcinoma of the renal pelvis, two operative specimens of diverticula of the bladder, and a kidney from a case of massive aseptic calculous disease.

## Rebichus.

### PRACTICAL PHYSIOLOGY.

THE textbook of *Practical Physiology*,<sup>1</sup> by CATHCART, PATON, and PEMBREY, may be regarded as the successor of the well known manual by Beddard, Edkins, Flack, Hill, Macleod, and Pembrey. Accepting for the moment the statement in the preface that "practical work should have a direct relation to medicine and, as far as possible, the experiments should be performed upon man," the present work is an admirable one for the purpose and will doubtless be largely used. From this point of view the sections on respiration and on the movements of the alimentary canal are excellent, as would be expected from their authors, Professor Pembrey and Dr. Hurst respectively. It is, however, somewhat disappointing to find so few exercises on the decerebrate preparation, on the lines of those in Sir Charles Sherrington's *Mammalian Physiology*, which, it should be remembered, are part of a course in physiology as a science. It is, no doubt, a matter of difficulty to provide such preparations for a large class, and the experiments must perforce be made in the way of demonstrations. Detailed instructions for such demonstrations would be useful to many teachers and would be welcomed in a new edition. There are many things of great practical importance which cannot be shown on man, while many which can be shown are much more obvious, more easily and accurately made, on lower organisms. Moreover, this attitude, if consciously taken, is apt to suggest the unscientific view that, apart from greater complexity, there are fundamental physiological differences between man and all other forms of life. The electrical changes in muscle, which form the basis of electro-cardiography, can be shown much more intelligibly on the despised frog than anywhere else. The main facts of permeability and the influence of various agents, such as anaesthetics, upon it, cannot be better demonstrated than on slices of beetroot!

The charge of lack of scientific insight has been brought against the medical profession, and it has often been noticed by the present reviewer that the chief defect in the education of the student is the failure to implant a knowledge of great general principles. It is remarkable how often a mass of details learned at the cost of much time and weariness follows naturally from a few fundamental laws. At this point we are inevitably led to ask: What then is the object of a practical course? Is it that the student may gain a real and concrete grasp of such basal facts as are referred to above? Or is it chiefly for the purpose of learning methods and processes which may possibly be used by him in the course of his subsequent practice? To take an illustration: Will the student be likely to have to estimate cholesterol in blood? The presence of cholesterol in this place is doubtless of importance for the membrane of the corpuscles, but would it not suffice to prove its presence and leave the exact estimation until required? These quantitative methods cannot be learned adequately without repeated practice. A similar remark might be made as to the measurement of the velocity of the nerve impulse. It is of great theoretical interest that this is not instantaneous; but the student is given a false idea of the accuracy possible in physical measurements of physiological processes and is content with a low standard when he has to use apparatus incapable of giving exact numerical results. Why not be content with showing that it takes some appreciable time? Of course it is to be understood that training for research is another matter, but in that case the student will naturally have the advantage of accurate apparatus.

Thus it seems to the reviewer that a practical course should consist chiefly of experiments which throw light on general principles. There are many experiments which have this character in addition to being of practical use afterwards. On the other hand, there are many that have little or no value in either way. Even from the strictly medical point of view, it is surprising to note in the book before us that there is no experimental work on haemolysis or permeability. Simple experiments on human blood corpuscles are most instructive in making clear the phenomena of osmotic pressure and the properties of membranes. The student is usually very hazy about these matters. It is also to

<sup>1</sup> *Practical Physiology*. By Professors E. P. Cathcart, M.D., D.Sc., F.R.S., D. Noel Paton, M.D., L.D., F.R.S., and M. S. Pembrey, M.A., M.D., F.R.S. London: Edward Arnold, 1922. (Demy 8vo, pp. 244; 265 figures. 13s. net. or in two vols., 10s. 6d. each net.)

be regretted that there are no exercises on the synthetic activity of enzymes, nor on the general nature of enzymic action, although there is no more difficulty in these than in the estimation of cholesterol, already referred to. They would afford the necessity for learning methods of estimating sugar in the course of experiments of interest in themselves. In this connexion it is surprising to find it stated on page 217 that isomaltose is probably the product of the reverse action of maltase. Even Dr. Frankland Armstrong has now given up this point of view. (See *Simple Carbohydrates and Glucosides*, 1919, p. 147.) Again, we find no simple experiments on the carriage of oxygen or carbon dioxide in the blood, nor on the maintenance of neutrality in this liquid. It will be seen that much of the kind of fundamental work contemplated can be done on man, and would not therefore be inconsistent with the avowed plan of the book. (The authors may be glad to have their attention called to a misprint on page 159, line 12 from the top, where we read "nitrate" instead of "nitrite".)

Opinions will probably differ as to the main function of practical physiology in the medical student's training. However this may be, the book before us will be found useful by the teacher and student though the price seems somewhat high. There is much to be said for the practice adopted in the elementary lessons by Professor Noël Paton of studying the microscopical structure of the tissues in relation to their functions. If it were not for practical difficulties, the chemical phenomena ought to be similarly worked out in connexion with the physical. This is the ideal method, especially for the junior student, and should not be impossible to arrange in such cases. To separate the detection of lactic acid in active muscle from the phenomena of contraction is unscientific, however necessary it may be for the detailed investigation of special points. To commence with the sense organs is a plan to be recommended, both theoretically and practically. On the other hand, the performance of experiments by the junior student without knowing what to look for is more questionable. As a training for research it is admirable. But the student is almost certain to have read about the facts in his textbook before doing the experiments, and it may be held that the chief object of elementary experiments is to give that grasp of reality which ensures confidence in the truth of what is stated in the textbook.

The statement in the first paragraph of the preface that medicine must be founded on physiology, that the study of the abnormal implies a knowledge of the healthy, should be sufficiently obvious. But when it is said that the "Institutes of Medicine" is the "older and better name for Physiology," some misunderstanding may arise. The authors are well aware that the scope of physiology is much wider than its application to medical practice. Medicine, along with agriculture, fisheries, practical dietetics, eugenics, and so on, stands in the relation of an applied science or art to the abstract or pure science or sciences on which it is based. As Claude Bernard pointed out, physiology is to be cultivated for its own sake, and stands alone in the various ways even if it had no practical applications in the various ways above mentioned. It would be well therefore to add the words "for students of medicine" to the title of the book under review. But, further, it almost looks as if a new profession were needed at the present time, the training for which would be chiefly directed to the preservation of health rather than to the cure of disease. It would require a more intimate knowledge of physiology and of the sciences on which it is founded than is possible to obtain in the time available when details of many special branches of pathology have to be studied. The medical therapist will always be necessary, but the "health officer," or whatever he may be called, would need a different training, in which physiology, both in its physical and chemical aspects—the latter being what is called "biochemistry"—would form the chief part.

W. M. BAYLISS.

### OXIDATIONS AND REDUCTIONS.

The second edition of *Oxidations and Reductions in the Animal Body*,<sup>2</sup> by H. D. DAKIN, will be welcomed by all workers interested in chemical physiology. As Dakin points out, although good progress has been made with the elucidation of the complexities of biochemical oxidations during

the eleven years that have passed since the publication of the first edition, no particularly new methods of attacking the problems have evolved. The problems which the monograph discusses in a most able fashion are amongst the most difficult and most interesting which can be found. It is becoming ever more evident that it is wellnigh impossible to discuss oxidation and reduction apart from other types of biochemical reactions such as condensations and hydrolysis. The problem which is really attacked in the book, then, is that of intermediate metabolism.

The volume opens with a most suggestive chapter on the fundamental nature of the changes which may take place during oxidation, and on the nature of the oxidizing and reducing agents found in the body, with a discussion of the methods requisite in their investigation. This is followed by very full chapters on the fate of the fatty acids, of the amino acids, of the carbohydrates, of the purins, and finally of the hydrocarbons, phenols, alcohols, etc. The chapter which has undergone the most drastic revision is that on the carbohydrates. It gives a most excellent review of the whole field in the light of the most recent investigations; for example, it discusses in some detail the mutarotation changes which seem to be of primary importance in the utilization of glucose in the animal body.

The monograph may be regarded as absolutely indispensable to those engaged in metabolic research. It ought, moreover, to be in the hands of every organic chemist, so that he may have a full appreciation of the problems of commanding interest which are to be found in the chemical processes within the living organism. The volume is provided with a very full bibliography. The price is extremely moderate.

### THE SURGERY OF THE WAR.<sup>3</sup>

[SECOND NOTICE.]

#### Abdominal Wounds.

An important and comprehensive description of the abdominal wounds of war was a very necessary thing. The good results obtained in South Africa by a policy of non-interference had always been rather a puzzle to the civilian surgeon. It was held that a bullet might traverse the abdomen without tearing the gut, but even in South Africa it was recognized that if the gut was torn the chances of recovery were small. Sir Cuthbert Wallace and W. W. Wagstaffe have written a very clear and comprehensive description of abdominal wounds. They show in Fig. 5 a chart of a number of bullet tracks which, against all expectation, coeliotomy proved to have missed the hollow viscera. But this chart is a record of rare happenings, and we trust that no reactionary will seize upon it to urge conservatism at some future date. However, even if the viscera escape perforation it is quite certain that intra-abdominal vessels will not. Haemorrhage was an outstanding cause of death, usually arising from the mesenteric vessels.

The ordinary military surgeon has less chances of becoming an adept at abdominal surgery than his civilian brother. This is in the very nature of things, and it is sure that any future war of any size (if one can contemplate such a thing) will again necessitate the employment of civilian surgeons on a large scale. Even so it is most necessary that the military man should have for reference so definitive an article as this. The charts of missile tracks are of more interest than appears at first glance. There is a short section on the action of projectiles that overlaps the first chapter in the book to a certain extent. The methods of injury are discussed and several instances given of rupture of underlying viscera in non-penetrating wounds. As might have been foretold, wounds of the small gut preponderated, colon next, then liver, and then stomach. The authors allow themselves some speculations on the physiological paralysis of the gut as a protective mechanism, and cite instances from their clinical records in support. The influence of time on the operative results is illustrated in a table; up to six hours the chances favoured the patient, but later than this they were against him. Thus the lesson of early operation is once more driven home, as it had already been in the case of appendicitis and

<sup>2</sup> *History of the Great War, Based on Official Documents: Medical Services. Surgery of the War*, Vols. I and II. Edited by Major-General Sir W. G. Macpherson, K.C.M.G., C.B., LL.D., Major-General Sir Cuthbert Wallace, Sir W. G. Macpherson, K.C.M.G., K.C.V.O., Major-General Sir Cuthbert Wallace, K.C.B., K.C.M.G., K.C.V.O., and Colonel Sir Crisp English, K.C.M.G. London: H.M. Stationery Office: 1922. <sup>3</sup> *Oxidations and Reductions in the Animal Body*. By H. D. Dakin, D.Sc., F.I.C., F.R.S. Second edition. Monographs on Biochemistry. London and New York: Longmans, Green, and Co. 1922. (Roy. 8vo, pp. ix + 176. 6s. net.)

gastric or duodenal perforation in civil life. The condition of the patient varied greatly. The wounded man was not always as prostrated as might have been expected, though in this there was great variation. With a pulse rate of 120 and over cases did badly, those with 100 did relatively well, though Gordon Taylor had some brilliant results with high pulse rates. The authors discuss the abdominal rigidity which so often accompanies low chest wounds, and point out how it may confuse the diagnosis. Besides shock, haemorrhage, and peritonitis, retroperitoneal sepsis was a not uncommon cause of death. The statistics of the results of operative methods varied considerably. On similar kinds of cases they were probably very much the same, although it is reasonable to expect those previously adept in abdominal surgery to get the better results. However this may be, there is no doubt that treatment along expectant lines was a hopeless failure. A mortality of upwards of 80 per cent. calls for some other methods. The average operative mortality remained about 50 per cent. The reader who sees this figure will very probably feel that the abdominal surgery of war is a disappointing thing. But a saving of thirty lives out of a hundred is something to be proud of, and these high mortality figures include a large number of cases which were poor risks at the time of operation. In specially favourable circumstances, and perhaps in specially skilled hands, much better figures than these may be hoped for. But it is no aspersion on the skill of our operators in France that a lower mortality could not generally be obtained. If a classification were possible into groups of cases in which, from the nature of the injury, the observer would expect recovery to be nearly certain, doubtful, or hopeless, we have no doubt that very different mortality percentages would be arrived at.

#### Wounds of the Viscera.

Wounds of the various viscera are described in detail, and some interesting points in the pathological anatomy of these injuries are illustrated. Several illustrations are given of the eversion of the mucosa, which was so characteristic an event when the stomach and small gut were lacerated. Resection is reserved for those cases where the small intestine is practically destroyed, suture of the independent perforations being advised as the best method when possible. Resection gave a 20 per cent. higher mortality than suture, though the extent of the initial injury was greater in the resection cases. End-to-end suture gave a higher mortality than lateral anastomosis, though again these figures by no means necessarily give accurate values for the two methods. Suture was sometimes effected by a single layer of sutures. It would have been interesting to know exactly how these cases fared. The question is apposite to the present moment in view of the recent work in Baltimore.

Injuries of the liver do not always call for operative treatment; wounds of the pancreas are not always associated with fat necrosis, and splenic injuries are much as in civil life, save for the often associated lesions of stomach, intestines, or kidney.

This part of the book passes insensibly into wounds of the urinary organs, which we take to be from the pen of Andrew Fullerton. It is illustrated by some of the beautiful drawings which have already appeared elsewhere. Intraperitoneal haemorrhage is a common accompaniment of kidney injury, in contradistinction to civil cases. Those very interesting cases of injury of a branch of the renal artery with local death of the kidney parenchyma irrigated by that branch are figured. Generally a conservative attitude in kidney injuries is recommended, local excisions and suture are advocated, though not all urinary surgeons will agree to this. For secondary haemorrhage removal of the kidney is very properly recommended. Of 13 such cases 4 died, but the amount of the bleeding is not stated. Wounds of the bladder were serious and usually associated with injury to the small intestine rather than the rectum. There appears to be no information on prostatic wounds. The writer has seen one with an injury of the prostatic sinus leading to sterility but not to impotence. A series of cystoscopic drawings of injuries of the bladder and of retained projectiles are of interest.

#### Gunshot Wounds of the Head.

Gunshot wounds of the head are dealt with by Wilfred Trotter and W. W. Wagstaffe. The importance of apparently trivial wounds of the scalp is once more insisted upon. The surgeon is wisely advised against opening the dura if that membrane is not lacerated. It may often be very tempting to incise the dura, but unless the surgeon has had exceptional

experience he had better refrain, as the risks of sepsis, in cases of this nature are so great. Injuries of the superior longitudinal sinus are discussed, and the clinical picture given by Sargent and Holmes is described; it is of somewhat obscure origin and is by no means always present. Foreign bodies remaining in a healed brain should be left alone unless symptoms and signs can be unequivocally traced to them. The paragraphs on unresolved cerebral contusion contain matter of a very controversial nature, and operations for its relief are not so generally successful as the authors indicate. The same may be said of the closure of cranial defects, the results of which are often disappointing. A few words on the contraindications for this operation should have been included.

#### Face and Jaw.

H. D. Gillies and B. Mendleson describe the restorative surgery of the face and jaw. The fine work done at Sidcup, and to a lesser extent elsewhere, in this most difficult branch of surgery has been of outstanding quality, and has definitely added much which will be of lasting benefit to surgery.

#### The Spine and Peripheral Nerves.

Injuries to the spine are discussed by Sir William Thorburn. The intensive study of the war injuries of the spinal cord has resulted in a great addition to our knowledge, and British neurology can look with content on what it has reaped in these fields. "Mais avouez," Babiniski has recently said, "que les acquisitions neurologiques nouvelles sont une bien faible compensation des misères déchainées par la catastrophe mondiale." The problem of operation in these cases tended to be confined to the question of cord damage. A very important point—the avoidance of primary wound infection by early operation—has not received the attention and consideration which it deserves. Mayo-Robson's cases of myelorrhaphy and grafting of rabbit's spinal cord are mentioned. Unfortunately Sir William Thorburn has not allowed himself a dogmatic opinion on this subject, although he has nothing good to say for cord suture in general. He passes on to consider injuries of the peripheral nerves. The variety, pathology, and symptomatology are briefly dealt with, and then the operative steps necessary for repair are described. Plastic operations on the nerves are not recommended, and the results of nerve grafting appear to be disappointing. Accurate end-to-end suture is the method of choice.

#### Injuries to Blood Vessels.

Another field in which very considerable advances have been made is that of injuries to the blood vessels. This is particularly true of the pathological anatomy of these lesions, thus founding a most substantial basis for the proper development of their surgery. A great deal of most important information will be found in these chapters, information most readily applicable by civilian surgery. The use of Tuffier's tubes is described, the value of ligaturing the companion vein as well as the artery is explained, and reasons given for the step. There are some valuable remarks on the cerebral complications following injuries of the carotid arteries. The frequency of cerebral softening from anaemia after ligation of the common or internal carotid arteries cannot accurately be judged from these cases, but it is worth while to note that intracranial complications were definitely found in 29.6 per cent. in one series and 33.3 per cent. in another. One case of ligation of both common carotids at an interval of forty-three days, with recovery, is mentioned. Two cases of death from the entry of air into the subclavian veins at operation are mentioned, and may serve as a warning to those who are sceptical of the seriousness of this accident.

#### Orthopaedic Surgery.

Two hundred pages devoted to orthopaedic surgery follow. They include a great deal of information on the treatment of fractures in general, and will be found of considerable interest to the civilian as well as to the military surgeon. It is sufficient warranty of the excellence of the advice given to say that it comes from the pens of Sir Robert Jones, E. W. Hey Groves, and other orthopaedists of note. R. C. Elmslie contributes an excellent section on amputations and artificial limbs. It contains some good advice on the best methods of placing flaps and on the best levels for amputation. The recommendations will often be found to be at variance with the older books. There is a general feeling that some change might with advantage be made in the amputations described in the students' textbooks. Chopart's

and Pirogoff's amputations, for example, give such unsatisfactory results that there is no object in continuing to give descriptions of them. The length of flaps classically described is too long for these days, when pain is neither laudable nor inevitable. A combined length of flap equal to the diameter of the limb is quite long enough, for redundancy of flap (particularly below the knee) may give as much trouble as deficiency.

The chapters on injuries to the neck, eye, and ear by Douglas Harmer, Sir W. T. Lister, and C. B. Goulden and Sidney Scott respectively, are of the quality that one would expect from such careful observers.

Each of the two volumes contains an index of somewhat archaic type, so that the reader often has trouble in finding what he requires.

GEOFFREY JEFFERSON.

### OPHTHALMIC SURGERY.

A LITTLE book entitled *Ophthalmic Surgery*<sup>1</sup> is of interest chiefly because it is a personal narrative of the experience of a former surgical specialist in India, Major NESFIELD, whose field of work in certain branches of ophthalmic surgery was of an extent which only India can provide. The author had almost unlimited opportunity of observing and treating trachoma, corneal ulcers, cataract, and glaucoma, and his observations on these subjects are of value.

The removal of cataract by the usual methods of extraction from the capsule he did not find satisfactory for India, neither did he obtain the results he desired by Smith's method of intracapsular extraction, the pressure needed too frequently causing loss of vitreous, with the dangers that entails. He gives an account of an operation which he has practised largely with very satisfactory results. The method is simple, his explanation of it is clear, and it is well worth trial.

The incision is made in the sclero-corneal margin, extending to almost one-half of the corneal circumference and providing a conjunctival flap. The cornea is lifted by means of the conjunctival flap, and a "ligatome"—an instrument rather like a small and flexible squint hook—is passed into the anterior chamber to its lower boundary and beneath the iris. The smooth point of the ligatome is turned down so as to reach the suspensory ligament; it is pressed upon that structure and swept to right and left so as to tear it through without rupturing the hyaloid membrane; gentle pressure is made upon the eyeball so as to bring the suspensory ligament forward and facilitate the engagement of the ligatome. Proof that the ligament is divided is seen in the rising up of the lens. If this does not happen the manoeuvre is repeated. When the lens is seen to rise attention is transferred to the iris; a minute button-hole iridectomy is made upwards at the base of the iris. That being accomplished, the lens is expressed, the upper lip of the wound is depressed by a spatula, then pressure is applied through the sclero-corneal margin to the lens at its lower border, and as far beneath it as is possible, by a blunt hook. Sometimes the lens somersaults and comes out still attached to the ciliary processes by the unruptured upper part of the suspensory ligament.

The author states that the rupture of the ligament is difficult in the young. It is this that makes intracapsular extractions so difficult in Europeans. The fragility of the tissues of the races of the Indian plains is notorious; it is only necessary to compare the skulls of Hindus and Europeans collected in the Royal College of Surgeons Museum to realize this point. The difference extends to the suspensory ligament of the lens; it is much tougher in Europeans than in Hindus. Hence the failure of European ophthalmic surgeons to obtain satisfactory results with the several intracapsular operations that have been evolved in India.

Some of the author's descriptions of other operations are less detailed and somewhat ambiguous. For operation on a Meibomian cyst he recommends an incision of "about half an inch long." Half an inch on an eyelid is a mighty large incision and likely to be dangerously destructive, especially when the direction of the incision is not specified. Some of the nomenclature used is misleading: the lacrymal canaliculi are systematically called lacrymal ducts, which they are not; and the true duct is variously written of as a "canal" and "duct." The method of removing the lacrymal sac is not quite happy. Squint operations are dismissed in a couple of pages, and the procedure advocated, which includes the "dividing the fascial expansions" of the tendon after tenotomy, is one that was formerly much practised but now generally avoided; the risks of a worse squint in the opposite direction and the deformity of a sunken caruncle are too great.

Despite these defects the book contains much of interest to an ophthalmic surgeon, for it is the record of a long experience in exceptional circumstances.

### THE VIRTUES OF SEA WATER.

Dr. J. JARRICOT has written a book<sup>2</sup> to demonstrate the value of treatment of infants suffering from grave disorders of nutrition by injections of sea water. The method is based on a theory formulated by Quinton, of which a good deal was heard a few years ago. We will endeavour to summarize Dr. Jarricot's statement of it as follows:

The first appearance of animal life on this earth occurred when the globe, in its process of cooling, had sunk to a temperature of about 44° or 45° C. (about 112° F.). It was at this point that the maximal protoplasmic activity was possible. Surrounded by a medium of sea water of a saline concentration of 0.7 per cent., the organisms multiplied rapidly; their bodies being at the same temperature as that of their environment. As, however, the temperature of the earth continued to sink, and as the oceans became more concentrated, certain changes occurred. Organisms arose which, first, were able to elevate their internal temperature above that of their environment, and, secondly, by interposing a selective membrane between their tissues and the sea around, succeeded in keeping their cells immersed in a fluid of the original concentration. This process was repeated time after time in such a way that those animals which developed latest in the scale of evolution are characterized by a body temperature closely approximating that at which life first became possible, and a blood plasma which is of probably almost the same osmotic pressure as that of the original oceans; on the other hand, those organisms which we know to be the most primitive are, with a few exceptions, distinguished by their poikilothermic mechanism of heat regulation, and by a plasma which is of the same concentration as that of present sea water—namely, 3.3 per cent.

The natural fluid in which the human tissues should be bathed is that of the primeval oceans, or—in the regrettable absence of that—sea water diluted down and rendered isotonic with blood plasma. It is this *marine serum*, as he calls it, with its content of no fewer than 28 elements, that is the ideal menstruum for the manifestation of the highest functional activity of the body cells.

Such is the author's argument. In practice he applies his treatment to infants who are suffering from retarded growth, arrested development, gastro-enteritis, cholera infantum, specific cachexias, or skin diseases. Though treated at a dispensary, the patients are cared for at home. Accurate measurements are first made, including the height, weight, and cranial perimeter; coefficients of atrophy and hypertrophy are worked out; and from these the extent of the departure from normal is ascertained. Food is given in the early months in the form of cow's milk, which is prescribed in such a way as to allow the infant to determine for itself the quantity it chooses to take—*à la rigueur de l'instinct*. At the same time subcutaneous or intramuscular injections of sea water are given, diluted till it is isotonic or somewhat hypertonic to blood plasma, and sterilized by filtration.

It is claimed that the effect of the sea water is to stimulate metabolism, to assist in the removal of noxious products, and to place the cells in a favourable environment for the adequate performance of their functions. Statistical data dealing with 105 children treated in this manner are carefully recorded. Photographs, charts, tables, and other figures showing recoveries from the worst conditions are reproduced in abundance. So excellent are the results that the author believes the "marine" treatment to be unequalled by any other system, and for this reason urges it not merely for those who are already diseased, but as a prophylactic measure of general application. On it he founds, in short, the science of puericulture.

There are two criticisms we would offer: First, that it is a matter for regret that he has failed to satisfy one of the most essential requirements of scientific investigation—namely, that of providing adequate controls. When two or more variable functions are at stake it is notoriously difficult to adjudicate on the influence of any one in particular. And though he has provided most useful tables of normal growth, yet he has neglected to observe the effects of an exactly similar treatment, differing only in the omission of the marine injections, on a comparable group of children. Secondly, the book itself is unnecessarily bulky, and is so badly arranged as to be at times almost exasperating. Had more attention been devoted to presenting the facts clearly in a logical sequence, and less to imbuing it with the spirit of propagandism, it would have been very much more readable. None the less the results reported are undoubtedly excellent. To those who may be disposed to investigate them experimentally in an impartial manner we would willingly recommend the book.

### "THE ELEPHANT MAN."

We noticed briefly last week the appearance of Sir Frederick TREVES's new volume, which promises to be one of the most widely read books of the season. *The Elephant Man and Other Reminiscences*<sup>6</sup> consists of twelve sketches drawn in the main from a perusal of old case-books. It is written with the skill and insight that we have learnt to expect from the gifted surgeon whose leisure years have been largely devoted to travel and literary craftsmanship. Most of these studies are cast in narrative form, and each tale is told in such a way as to bring out in sharp relief some aspect of human life and character. "What a strange company they are," the author remarks, "these old patients who crowd into the surgeon's memory after a lifetime of busy practice! There they stand, a confused, impersonal assembly, so illusive and indistinct as to be little more than shadows. Behind them is a dim background of the past—a long building with many windows that I recognize as my old hospital, a consulting room with familiar furniture, an operating theatre, certain indefinite sick-rooms, as well as a ward in which are marshalled a double row of beds with blue and white coverlets."

A note of tragedy and terror dominates many of Sir Frederick Treves's stories; others are frankly pathetic; and in several we perceive an undercurrent of sarcasm. His description of the old receiving room of the London Hospital, with its racy portrait of the receiving-room nurse of half a century ago, is an example of how a vivid effect can be conveyed with economy of language; the rich humour of this piece will appeal to every medical man. But there are passages in this and other parts of the book that will surely upset the sensitive general reader. For the most part, however, realism is tempered with restraint, though the episode of the young surgeon who operated upon (and killed) his wife is so distressing that we should prefer to regard it as fictitious.

The first chapter, which gives its title to the volume, tells the story of John Merrick, a young man afflicted by so terrible a deformity that he could not venture out of doors by daylight. In 1884, when he was being victimized by a showman in a room off the Mile End Road, this unfortunate creature was discovered by Mr. Treves, who two years later

found a home for him in the London Hospital; he was then helpless, exhausted, and destitute. There he received the utmost kindness from the surgeon who had rescued him, and from many others, until his death in 1890.

By reason of his dreadful deformities Merrick was known as "the elephant man," and our readers may be interested to have a few further details of his condition. He was twice exhibited before the Pathological Society by Mr. Treves, and full accounts, with reproductions from photographs, appeared in the *BRITISH MEDICAL JOURNAL* of December 11th, 1886

(p. 1188), and again in the issue of April 19th, 1890 (p. 916). Our present illustration, showing Merrick's condition shortly before he died, is derived from the latter article. His complaint was not elephantiasis (as most people supposed), but a complication of gross hypertrophy of certain bones, with pachydermatocoele and papilloma of the skin. The surface of the skull was covered with huge rounded exostoses. This enlargement of the bones of the head and the osseous deformities of the right arm and the lower limbs seemed to be congenital; disease of the left hip-joint during youth caused permanent lameness. When a child his skin was merely thickened, loose, and rough. As he grew up papillary cauliflower-like masses developed, especially over the back, the nates, and the occiput; in the right pectoral region, the posterior aspect of the right axilla, and over the buttocks the affected skin formed heavy pendulous flaps. The left arm and other portions of the body surface remained free from disease, and in no part was there any naevoid growth. From 1885 until his death the disease rapidly advanced, though his general health kept relatively good. The bony masses and the fungous folds of integument grew

THE ELEPHANT MAN IN 1889.

steadily; the head became larger and larger until at length he could scarcely hold it up. Then one night, as he slept in his customary crouching posture, the ponderous head fell back and dislocated his neck. A *post-mortem* examination was not allowed.

Such in brief were the facts of the case. Merrick's benefactor now tells something of the inner life of this poor misshapen being, more hideous far than Caliban, yet whose spirit, "if it could be seen in the form of the living, would assume the figure of an upstanding and heroic man, smooth browed and clean of limb, and with eyes that flashed undaunted courage."

<sup>6</sup>*The Elephant Man and Other Reminiscences*. By Sir Frederick Treves, Bt., G.C.V.O., C.B., LL.D. London and New York: Cassell and Co., Ltd. 1923. (Post 8vo, pp. 222. 7s. 6d. net.)

### NOTES ON BOOKS.

We have recently received from the Cuban medical journal *Asclepios* its special issue of July-September, 1922, devoted to gastro-enterology. Dr. F. Torralbas contributes clinical notes on amoebiasis and trichocephaliasis. Dr. R. G. San Martín describes a case of perforated gastric ulcer of the lesser curvature. Dr. F. S. Ramos discusses gastric heterochylia. Dr. G. A. Cuadrado writes on the chemical biology of digestion, and the issue fitsly closes with a gastro-enterological poem by a subject of Lane's link.

We have received the first issue of *Archivo de Medicina Legal*, a Portuguese journal devoted to medical jurisprudence, and edited by Dr. Azevedo Neves, professor of that subject in the Lisbon Faculty of Medicine; he has the support of more than eighty collaborators in Portugal, Spain, and Spanish America. The first two numbers of which this issue is composed contain twenty articles of medico-legal interest, of which the following call for special mention: New tests for hydrocyanic acid, by J. Peset and J. Aguilar; the importance

of leucocytes in the medico-legal determination of the origin of blood, by Ramón Alvarez de Toledo y Valero; cases of spontaneous rupture of the heart, by H. Parreira; criminality in Lisbon, by A. Morgado; the practice of medicine in Portugal, by A. da Cruz; the psychological masochism of Sister Marianna Alcofrado, and the comparative study of the ages of victims of rape and their aggressors, by A. d'Aguiar; and a Portuguese bibliography of medical jurisprudence, by L. Gomes.

The second edition of the book, *Physical Diagnosis*, by Professor W. D. ROSE, of the University of Arkansas, was reviewed in our columns on February 4th, 1922. We have now received the third edition; the text has been subjected to revision, especially in the sections dealing with the circulatory system and blood pressure, but the book remains essentially the same as before.

<sup>7</sup>*Physical Diagnosis*. By W. D. Rose, M.D. Third edition, revised and enlarged. London: Henry Kimpton. 1923. (Med. 8vo, pp. 753. 21s. figures. 45s. net.)

## THE MNEMIC PRINCIPLE APPLIED TO BIOLOGY AND PSYCHOLOGY.

BY

SIR FREDERICK MOTT, K.B.E., F.R.S.

THE book on "the Mnemo" (μνήμη, memory) by the late Richard Semon of Munich<sup>1</sup> is a work of great importance and scientific interest, for even if some of the premisses upon which the author founded his theory that memory, habit, and heredity were factors of one common principle (the mnemonic principle) are either inconclusive or even to some biologists unacceptable, nevertheless the attempt he made cannot fail to have a profound influence upon psychology and biological science.

This mnemonic theory is not new; four independent attempts to connect the phenomena of memory, habit, and heredity prior to Semon's had been made by Hering, Samuel Butler, F. Laycock, and Henry D. Orr, but not one of them seems to have made any real influence upon contemporary scientific thought, for they all omitted to explain definitely why such dissimilar processes should possess in common an obviously repetitive nature. Bertrand Russell, in his recent book *Analysis of Mind* (Chapter IV, Influence of past history on present occurrence in living organisms), adopts the term "mnemonic phenomena" for those responses of an organism which, as far as observed facts are concerned, can only be brought under causal lines by including past occurrences in the history of the organism as part of the causes of the present response.

Semon points out that the immediate effect of stimulus upon irritable organic matter is excitation, but that the excitable condition manifested is really only half the effect produced, for although the irritable substance after the cessation of the stimulus returns to an indifferent state there remains a primary latent modification, a physico-chemical change, which Semon terms an "engram." The engraphic effects of a stimulus, then, are: (1) excitation, (2) an engram. The capacity of an organic substance to be engraphically affected constitutes the mnemonic principle.

The engrams of an irritable substance are the altered dispositions of it towards recurrence of states of excitement produced by the original stimuli. The organic substance, in consequence of specific engraphic action, shows itself specifically predisposed to those states of excitement which were induced by the original stimulus or by stimuli in juxtaposition, coacting either simultaneously or successively. Coacting stimuli received by the organism are reproduced mnemically in juxtaposition. Thus two experiences A and B occurring simultaneously ecphorize (ἐκφωρῶ or ἐκφέρω, to carry out or away) A and B in simultaneous juxtaposition. Experience A can ecphorize B, or the converse. If, however, experiences A and B are successive, A can ecphorize B but B cannot ecphorize A. This is quite obvious in reciting a poem. In singing a song we know that the music can ecphorize the words and the converse, because the word and the tune are simultaneous. An interesting fact in connexion therewith is that cases of aphasia have been recorded in which a song could be sung right through, although the words could not be uttered without the musical tones. I published an interesting case of this in a soldier who was blind and suffered with right hemiplegia and aphasia in consequence of a bullet wound of the brain. Recently Professor Bianchi has published a remarkable case of a man with thrombosis of the left middle cerebral artery, causing complete aphasia, who was able to sing popular Neapolitan songs. Most people know how easy it is to sing a song after it has been started correctly, and how difficult it is to memorize the tune and the words if interrupted; indeed, it is necessary often to begin the bar or the verse again. A well known song when once started voluntarily is followed by a successive ecphory of a series of associated tonal and articulate engrams. The series of incoming auditory and kinaesthetic stimuli successively and automatically ecphorize the corresponding motor engrams in the form of a chain of reflex patterns. Attention, not being directed to correctness of tone or the memory of the words, can be devoted to expressive feeling and clear diction. Awareness of the correctness of the words and tone only enters clear consciousness demanding attention when a slip or fault occurs.

The individual stimulus does not liberate one isolated synchronous excitation and make an isolated engram. Such detachment is wellnigh impossible in nature. What we find is this: that a simultaneous excitation complex, as such, after the lapse of the synchronous excitations is engraphically fixed in its totality. That which remains is a simultaneous "engram-complex." This simultaneous complex is the product of the excitations resulting from the entire energetic condition, and by energetic condition Semon means not only the external energies affecting the organism, but also its internal energetic state. The latter is just as important as the forces acting on it from without.

Because only a small fraction of a simultaneous excitation complex manifests itself clearly on mnemonic reproduction we get the impression, not of the recurrence of a former complete energetic condition, but only of a specific section. The internal energetic condition of an organism varies greatly at different times, so that the same external energetic condition produces at various moments altogether different simultaneous excitation complexes.

*The Mnemic Principle Applied to the Three Primal Instincts.*

I will now endeavour to apply the mnemonic principle to the three primal instincts. The following quotation from Bertrand Russell (*Analysis of Mind*) shows that the application of the mnemonic principle to the primal instincts of self-preservation, preservation of the species, and gregariousness is accepted by this profound psychologist.

"The response of an organism to a given stimulus is dependent upon the past history of the organism, and not merely on the present stimulus and the hitherto discoverable state of the organism. In the case of living organisms practically everything that is distinctive both of their physical and mental behaviour is bound up with this persistent influence of their parts. Further, speaking broadly, the change in response is usually of a kind that is biologically advantageous to that organism."

An inherited permeability or tendency to "permeability of neuronic routes" (Lloyd Morgan), synonymous with "engrams," connected with the primal instincts when appropriate stimuli arise, predetermine the instinctive behaviour of animals. For this reason chicks as soon as they are hatched seek and pick up food. In the human being sucking is the only complete instinctive act; the instincts of man are nearly all overlaid and consolidated by acquired habits. Owing to the great development of his psychic neuronic system man, moreover, is enabled to inhibit and control instinctive reactions.

Now instinctive neuronic routes are permeable because the chains of neurones which form the routes have, in the long procession of ages of evolution, engraven in them engrams of successively repetitive stimuli, thereby permitting a stimulus appropriate to one of the three primal instincts (self preservation, preservation of the species, or gregariousness), immediately or very readily to excite them successively, and bring about a specific inherited series of purposive reactions—in fact, a chain reflex. As all reactions are primarily sensory-motor reflexes, once the stimulus starts a motor reaction an incoming proprioceptor sensory stimulus from the parts moved correspondingly occurs to act as an incoming stimulus to arouse successive latent engrams connected with the instinctive purposive and unforeseen end (see figure). For instinct is blind.

*Instinct of Self-Preservation.*

With respect to self-preservation we may take an example given by Semon. A dog barks with delight to fetch a stone which you pick up and throw for it to fetch and carry, and every time you bend down to pick up a stone the dog barks with delight in anticipation of fetching and carrying it; but if, instead of throwing the stone for him to fetch, you throw it at the dog and it hits him, a nociceptor stimulus of the skin is produced and the dog, when next he sees you bend down, instead of barking with delight and wagging his tail, runs away howling with tail down. Clearly the engrams produced by nociceptor stimuli are more easily revived than engrams associated with beneceptor stimuli. Adopting, again, the term of Lloyd Morgan of "permeable neuronic routes" for engrams, we may assume that the neuronic routes of nociceptor are innately more permeable than beneceptor stimuli, which hypothesis is supported by Sherrington's experiments on the spinal animal.

We see in this observation that the visual stimulus of bending down ecphorizes a previous painful experience, but

<sup>1</sup> *The Mnemo*. By R. Semon. Translated by L. Simon. London: G. Allen and Unwin, Ltd.; New York: The Macmillan Co. 1923. (Demy 8vo pp. 29). 18s. net.]

before painful experience of the stone striking the skin can occur a protective behaviour, accompanied by the emotional expression of fear, is excited. This fact shows (1) that a complete repetition of the original condition is not necessary in the application of the mnemonic principle, and (2) that painful stimuli have a more powerful influence in preservation of the individual than pleasurable stimuli.

#### The Sex Instinct.

A subtle chemical stimulus such as the sexual hormone circulating in the blood may be regarded as the initial stimulus which arouses inherited latent engrams connected with propagation; and in animals the behaviouristic series of the chain of reflex patterns once started proceeds successively through permeable neuronic routes to a purposive end. The sex instinct in human beings is likewise automatically aroused by specific male and female sex hormones. The subjective manifestations are at first vague, uneasy feelings with an unconscious desire for relief; this unconscious vague spontaneous desire sooner or later arouses latent engrams of conscious desire and purposive behaviour towards the opposite sex, such as endeavours to attract attention by display accompanied by the sentiments of pride and vanity, which finally under normal conditions culminate in a passion (love) in which the male plays the active part and the female the apparently passive part, though it is the apparent passivity of the magnet.

#### The Gregarious or Social Instinct.

As an example of the inherited instinct of gregariousness a dog in chasing a rabbit barks instinctively to call up the pack because there are pre-organized permeable neuronic routes associating olfactory and visual images of the chase with the neuronic structures connected with barking, although the dog by barking may defeat the purposive end of capture of his prey. How different is the behaviour of the solitary hunter, the cat!

#### The Mnemic Principle Applied to Ontogenesis.

Can this mnemonic principle be applied also to ontogenesis? *A priori* we should expect that it could, for ontogenesis is in a measure a recapitulation of phylogenesis. Progressive evolution in the animal series depends upon the establishment of pre-organized latent engrams (connected with the three primal instincts) in the body as a whole, but in the nervous system in particular. These latent engrams which are necessarily ephorized are so adapted to feeling and behaviour of *homo sapiens* for the preservation of the individual and the species as to promote natural selection and survival of the fittest. The male and female gonads are each respectively the bearers of latent specific dispositions peculiar to species, race, and familial ancestry. The initial stimulus to an orderly sequence of stimuli for developmental formative structural activities is the conjugation of the male and female gonads; once started there follows automatically an ephory of latent engrams peculiar to species, sex, race, and ancestry by stimuli which have been successively repetitive during the long procession of ages of evolution. The engrams of species are immutable, and in a great measure also those of race; but the particular mental and bodily characters of the individual depend upon latent engrams derived from race, and those due to familial ancestry are plastic, therefore mutable, and most subject under the influence of environmental stimuli to variations.

#### The Mnemic Principle Applied to Habit.

Habit is distinct from instinct. Habitual actions are acquired by conscious voluntary attention to trial by failure and success of sensory-motor activities for a purposive end, repeated until a successive series of engrams or permeable sensory-motor neuronic routes has been established; and it is then only necessary to will the first movement for the rest of the reflex patterns to follow automatically in orderly sequence until the end is attained. In an habitual action, once the chain of reflex patterns has been initiated, conscious voluntary attention is no longer required; but should any interruption or failure of perfect ephory of successive engrams occur, there is awareness, and effort is made to supply, correct, or adjust the defect. This may be explained by a diagram showing the permeable neuronic routes which repetitive successive stimuli have created.

#### The Mnemic Principle Applied to the Influences of Inherited Dispositions.

The transmission of acquired characters is a heresy to most biologists, but Semon says (p. 84): "In a limited but fairly imposing number of cases we are able to influence inherited dispositions so effectively that the newly added engram not

only remains in force during the individual life of the organism, but is transmitted to the offspring." Attention is directed to certain experiments, the most convincing of which are those of P. Kammerer:

"The so called fire newt, *Salamandra maculosa*, which is viviparous, ordinarily gives birth to larvae measuring on the average 25 mm. and carrying gills. The broods may number anything from 14 to 72. These larvae are deposited in the water, and there pass a long transitional stage, until, after several months, they lose their gills, leave the water, and completely change into land newts. By change of conditions Kammerer succeeded in forcing the females to retain their offspring for a longer time in the uterus. Then, by repetition of coercion, these re-

tarded parturitions became habitual. In order to induce the females that had previously borne normally to retain their offspring in the uterus beyond the usual time, Kammerer kept them from the water-trough in which they would ordinarily have deposited their larvae." Kammerer now reared young, born of animals which had reached the highest stage of habitual late parturition, and mated them with each other. He then subjected the females to normal conditions during pregnancy, by supplying them with a water-trough and moist air, and by maintaining them at a moderately high temperature. Although there was no longer any external coercion to late parturition, the creatures departed from the normal breeding mode of their species, and without exceptions from the beginning made late and sparse births.

As the validity of these experiments of Kammerer and others, upon which Professor Semon based his views of the possibility of the influence of environmental stimuli upon the germ cells, is doubted by biologists, I will quote the following verbal communication made to the meeting of the Royal Society on January 18th, 1923, by Professor E. W. MacBride, F.R.S.:

"It is well known to zoologists that during the last fifteen or twenty years a series of experiments have been carried out by Dr. Kammerer at Vienna, which tend to show that acquired qualities, or, in other words, modifications of structure induced by modified habits, are inheritable. The results of these experiments have been received with much scepticism, both here and on the Continent, and the *bona fides* of Dr. Kammerer has been called in question.

"One of the most interesting of his experiments was in inducing *Alytes*, a toad which normally breeds on land, to breed in water. As a result, after two generations, the male *Alytes* developed a horny pad on the hand, to enable him to grasp his

Diagrammatic representation of the formation of a serial-response habit (after Dunlap, slightly modified). The series of responses is at first the result of the successive stimulation of the distance receptors shown at the top of the figure. During practice this stimulation is accompanied by the stimulation of proprioceptors in the acting muscles. This proprioceptive stimulation gives rise to nervous impulses that are drained as indicated by the arrows into the acting system, and in time the series of responses may be elicited by these movement-produced stimuli, only the first of the distance receptor stimuli being necessary. M., Muscles; P., proprioceptors; M.S., muscle spindles; T., tendon joint.

slippery partner. It has been admitted by Kammerer's critics that if he could demonstrate this pad he would to a large extent succeed in establishing the validity of his results.

"This summer, at my request, Mr. J. Quastel of Trinity College, Cambridge, when in Vienna, interviewed Kammerer, and was shown by him one of these modified males. . . . Subsequently, at my request, the Zoological Society dispatched Mr. E. Boulenger on a visit to Vienna. He too saw the modified male, and was assured by Przibram, the head of the Biological Institute, that all Kammerer's experiments had been done under his (Przibram's) supervision, and were perfectly genuine."

Semon from these and many other experiments claims "that a stimulus affecting the irritable substance of an organism and inducing excitation therein may in some cases affect also the germ cells, leaving demonstrable engrams behind, but that in other cases the germ cells are unaffected."

He claims that the mnemonic theory does not conflict with the Mendelian doctrine. He asserts that "it is not Darwin, but Weismann, who has been refuted by the more recent data acquired in the course of experimental research into the laws of heredity."

In the following statement he shows how the mnemonic principle may be applied to natural selection and survival of the fittest:

"In the mneme there is to be found a conserving principle which is indispensable for organic development, in so far as it preserves the transformations which the external world unceasingly creates. Its conserving influence is, of course, restricted by that indirect factor of the external world, Natural Selection, for, in the long run, only fit transformations survive."

### THE INDIAN POLITICAL DEPARTMENT.

IN a note on the recent retirement of Major-General Sir William Edwards, the late Director-General of the Indian Medical Service, it was stated that he had passed great part of his service in the political department. This statement probably conveyed little or no information to readers in this country, to whom the nature of the Indian Political Department is unknown. This department corresponds roughly to the British Diplomatic Service. It deals with the relations of the Government of India with the independent countries bordering on India; Afghanistan, Tibet, Nepal, etc., and with the numerous semi-independent Indian native states. It has always been considered the most important department of the Government of India. In the distribution of portfolios among the members of the Indian Government the Viceroy retains that of the political department in his own hands. Under him its immediate head is the Foreign Secretary, of late years always a member of the Indian Civil Service. It has hitherto been recruited from officers of the I.C.S. and of the Indian army in about equal proportions, but for some years past the tendency has been to increase the number of civil officers at the expense of the military. But while these two services have always contributed the greater part of the personnel of the political department, the Government have always exercised the right of taking officers whose services were considered useful or necessary from any department of Indian service, medical, public works, police, etc. The highest appointments in the department are the chief commissionerships of British India and of the North-West Frontier Province; the agencies of the Governor-General, Central India and Rajputana; and the residencies of Nepal, Haidarabad, Kashmir, Mysore, and Baroda. After them come second class residents, political agents, and political assistants, the whole forming a regular graded service, with regular promotion from grade to grade. The Government, however, frequently fills up the highest appointments from outside the department. Service in the political department has always been the quickest and best route to success and fame. Many of the best known names in the middle history are those of political officers, especially in the India of the nineteenth century, while the British Empire in India was rapidly expanding: Sir John Malcolm, a century ago; Sir Alexander Burnes, assassinated at Kabul in 1841; Sir Herbert Edwards, of Punjab fame; John Nicholson, who fell in the siege of Delhi; and, greatest of all, the Lawrence brothers, John Lord Lawrence and Sir Henry Lawrence, killed at Lucknow, were all "politicals." All of these, except John

Lawrence, were military officers. Coming nearer our own times, we may add the names of Sir Louis Cavagnari, killed at Kabul in 1879; Sir Robert Sandeman, of British Biluchistan; and Sir Francis Younghusband, who is happily still living.

In addition to the executive officers of the political service, every political residency and agency, except a few of the smallest, has a medical officer attached to it. These posts have always been filled from the Indian Medical Service, and when it is stated that an I.M.S. officer is in political employ, or in the political department, this means that he is attached to the department as a medical officer, not that he is an executive political officer. As a rule, the medical officer enters political employ fairly young and is posted to one of the less popular stations, rising gradually to pleasanter and more lucrative appointments. And some of the higher posts under the Foreign Office are among the most important and lucrative medical appointments in India. But, as in the case of executive officers, it sometimes happens that a senior medical officer is appointed from some other branch of the medical service direct to one of the most important posts under the Foreign Office. As an instance may be mentioned the late Colonel Lawrie, who was transferred from being Professor of Surgery at Lahore to be Residency Surgeon at Haidarabad, a post which at that time was usually considered the best medical appointment in India.

As stated above, the Government has always selected for employment in the political department officers of any service whom they considered likely to make successful political officers. And, from time to time, many officers of the I.M.S. have been so selected, usually after a period of service as medical officers of the department. A few names may be mentioned as the best known, though there have been many others. Surgeon Graeme Mercer, of the Bengal Medical Service, in the early years of the nineteenth century was Resident at the Court of Scindia, the Maratha chief, ruler of the then independent state of Gwalior. The well-known work, *Letters from a Maratha Camp*, was written by Lieutenant (afterwards Colonel) T. D. Broughton, while commandant of the Resident's (Mercer's) escort. Sir John McNeill, while an assistant surgeon in Bombay, was appointed medical officer to the British Mission in Persia in 1820, and in 1835, after fifteen years' service in that capacity, became secretary to the embassy. He retired from the medical service in 1836, and in the same year was appointed Minister Plenipotentiary to Persia, holding that post for six years, till 1842. On April 15th, 1839, he received the Grand Cross of the Bath, being the only I.M.S. officer who has ever gained that honour. He lived till May 17th, 1883. Percival Lord, also of the Bombay service, after accompanying Sir Alexander Burnes to Kabul, in 1836, when the British restored Shah Shuja to the throne of Afghanistan and occupied the country, in 1839, was appointed Political Officer on the Uzbek frontier, where he was killed in action in the battle of Parwandara on November 2nd, 1840. Sir John Spence Login, of Bengal, after serving with D'Arcy Todd at Herat, in the Afghan war, 1839-42, joined the political department. He was appointed tutor to Dulip Singh, the child Maharajah of the Punjab, deposed in 1849, after the second Sikh war. Deputy Surgeon-General Henry Walter Bellew, author of many works on Afghanistan, was at Kandahar during the Mutiny, and afterwards served for several years in the political department, being chief political officer at Kabul during the second Afghan war, but later left it for the smoother paths of the sanitary department. The last I.M.S. officer who served as an executive political officer was the late Sir George Robertson. He entered the Bengal Service in 1878 and joined the political department ten years later. He was chief political officer in the Hunza-Nagar campaign of 1891-92, and afterwards political agent of Chitral, a small state on the North-West frontier, and as such went through the siege of Chitral, for which he received the K.C.S.I. He retired on October 12th, 1899, and since then the I.M.S. has not been represented in the executive ranks of the political department. After his retirement Robertson was M.P. for Central Bradford for ten years, from 1906 till his death on January 2nd, 1916.

THE seventy-fifth anniversary of the Société de Biologie of Paris will be celebrated on May 26th. The subjects to be discussed are: generation and fecundation, introduced by A. Brachet; physiological action of potassium and calcium, introduced by H. Zwaardemaker; the problem of immunity in invertebrates, introduced by J. Cantacuzène.

SATURDAY, FEBRUARY 24TH, 1923.

### THE SCHEME OF LIFE.

CIRCUMSTANCES conspired to make the celebration, last week, of the memory of John Hunter by the Royal College of Surgeons of England an occasion of more than usual distinction. In the afternoon the Orator gave an address in which, as those who read it in our columns last week will have noted, certain facts of nature were related and discussed in the Hunterian manner, and in the evening Mr. Rudyard Kipling carried away his audience—which has included a multitude greatly exceeding the guests of the College who heard him—to the border-line of science and the misty world of the spirit. Sir John Bland-Sutton is very competent—no man to-day so competent—to understand and therefore to make plain to others John Hunter's attitude towards the facts and the problems of nature; and, as may be read at length in the full report of his speech published at page 346, Mr. Kipling proved that he had a vivid understanding of the motives that actuate the students of the science and the practitioners of the art of medicine and surgery.

By way of a parable Mr. Kipling set forth a quality of man's mind, very commonly overlooked by persons who construct new social systems—that quality which makes man desire to know the how and the why of the working of nature about him and in him. The puppy destroys for fun, the child for fun too sometimes, but more often in the desire to find out how the thing works. Man, Mr. Kipling said, had always searched, in spite of the disabilities due to his own nature, and the restrictions imposed on the searcher by his fellows. He had searched openly or furtively, in safety or at the risk of his life, and had gone up against the darkness that cloaked him and every act of his being. Now the quest was called scientific research, but "it was the old quest under a new name." This is profoundly true, but Mr. Kipling might have gone on to say that, in his search for the spark Brahm hid, man has been impelled to try to understand the universe, inasmuch that astronomers speak of young stars and old, not because they suppose the young to be newly born, but because they are so far away that the light from them has taken aeons to reach us. When the light started they were young, now they must be old or at least middle-aged, as are the stars half as near again, whose light reaches us in half the time.

The point we would make is that man possesses an inborn appetite for knowledge; it is strong in some men, weak in others, but present, more or less well directed, in all. In Hunter it was voracious. He hungered for new facts, and recorded them even though he could not guess at their relation to other facts he was observing and recording. Hunter began as an anatomist, and throughout his life his main interest was always in structure. There can be little doubt, as suggested in the oration, that he began to preserve the specimens he dissected in order to serve the needs of his brother as a teacher; but as his knowledge and his collection grew his outlook enlarged. He perceived the existence of system throughout animated nature, and conceived his collection as an "illustration of life exhibited in the vast chain of organized beings, living and extinct, by a display of the various organs in which the

functions of life are carried on." Embryology attracted him, and he spent much time and labour in its study, but he seems now in both respects—his collection and his embryology—like one wandering in a wood, eagerly observing all within his range of vision, though without a sense of direction, but yet recording his observations with an inner conviction that they must eventually serve to make plain the path. While studying and dissecting animals the idea, indeed, arose in his mind that living things could be arranged in a physiological series, but he did not possess the key which the doctrine of evolution has placed in the hands of every student to-day. He had the hall-mark of a leader in scientific investigation, for he did not slur over exceptions, but gave special attention to them; though he had to be content with recording and preserving, yet he was confident that his facts would some day fall into their place in our conception of the scheme of life.

Lord Balfour, in bringing to an end last week the long course of Gifford lectures he has been giving at the University of Glasgow, attempted the remoter question of how the whole was started and is directed. He said that it was necessary to bring in at the beginning, and as transfusing the process from beginning to end, some form of reason, some element of purpose, and he did not shirk the use of the word "design," nor hesitate to affirm that theism must indubitably be a part of any system which claimed to avoid the fallacy that unreason had produced reason. At the same time he told his audience that there was nothing to fear from science, but that they should press on science by every means in their power; the warning ought not to have been necessary, for if design be a truth then no truth of science can be in conflict with it.

### MORTALITY IN OCCUPATIONS.

THE fourth part of the Supplement to the Seventy-fifth Annual Report of the Registrar-General, which has just been published, is a welcome though belated document. It is the sixth evaluation of mortality in occupations made in the General Register Office and concerns the years 1910-12. Some important improvements in detail have been made, but the general lines of the inquiries of 1890-92 and 1900-2 have been followed. The essential principle is to relate the deaths registered in three years, of which the census year is the middle, to the enumerated populations of the census year. The method of derivation of rates of mortality involves some difficulties of interpretation. In a few cases—for instance, that of an occupation such as seafaring, which is not carried out at home—the enumeration of deaths is likely to be more complete than that of those liable to die; what the actuary terms the "exposed to risk." In all cases—the specification of occupation being obtained in one way for "the exposed to risk" (namely, from the census schedules filled in by the heads of families), in another way (namely, from the information supplied to the registrar) for the deaths—there may be a lack of homogeneity between the numerator and denominator of the fraction which is the death rate. Further, there is the inevitable difficulty of deciding which is the horse and which the cart; whether, let us say, coal mining is a healthy occupation, or whether only healthy men can be coal miners. Lastly, there is the ambiguity of a classification partly occupational and partly industrial. To quote the report: "The classification is, on the whole, rather of an industrial than of a strictly occupational nature; and thus obscures in many instances the full effect of

<sup>1</sup> Supplement to the Seventy-fifth Annual Report of the Registrar-General for England and Wales. Part IV. H.M. Stationery Office. 12s. (pp. 102, 12s. 6d. net.)

dangerous processes or operations. It deals with such groups, for instance, as men making cutlery, or motor chassis, or pottery; but it does not distinguish how many of these men are grinders, or sand blast operators, or lead glaze workers, and thus precludes any estimation of the real risk to life involved in these processes by themselves. . . . It remains to be seen whether the renewed efforts made in the preparations for the 1921 Census to provide for the separate treatment of dangerous processes by framing the classification on genuinely occupational lines throughout will achieve success in practice."

When all these objections have been admitted the fact still remains that this document is one of the most important State papers issued, and should provide food for thought and material for comment to medical statisticians and hygienists for some time to come. At present we can but touch lightly a few points, but hope to return to the subject at an early date.

As a whole, the mortality of all occupied and retired males in 1910-12 was much below that of 1900-2; there was an improvement of 21 per cent. on the standardized rate of 1900-2. Not one of the specified occupations had 100 per cent. of the earlier rate; lead miners—a very small group—came nearest to equality with 98 per cent. The medical profession improved slightly more than all occupied and retired males, having in 1910-12 a mortality which was 73 per cent. of the rate in 1900-2. The greatest improvement of all was in the group general shopkeepers, with only 55 per cent. of the 1900-2 figure. Of important causes of death, cancer and valvular disease of the heart showed increases; phthisis and the non-tuberculous respiratory diseases heavy decreases.

A consideration of the details shows a certain solidarity of diseases. For instance, if the occupations in which cancer is high or low be noted, the rates of mortality from all other causes are found to tend on the whole to be also high or low. Of 18 fairly large groups which had a mortality from cancer at least 25 per cent. in excess of the rate on all males, there were only 3 which had a mortality from all other causes below the standard. Of 18 occupations with a cancer mortality at least 25 per cent. below the mean, one only had a rate for other causes above the average.

As usual, occupations exposing the workers to the effects of alcoholism were characterized by excessive mortality. In terms of the standard population of males aged 25 to 65, taking the general mortality in this standard as 100, beer bottlers and cellar-men exhibited the moderate excess of 23, brewers were up to 129, inn and hotel servants reached 148, and hotel keepers, publicans, spirit, wine, and beer dealers 160. The special sub-group bar-men had more than twice the standard mortality (218 per cent.). Motor car and van drivers enjoyed just 50 per cent. of the average mortality, easily beating even clergymen, priests, and ministers with 55 per cent. Physicians, surgeons, and registered practitioners were very slightly worse than the standard under cerebral haemorrhage and "other diseases of the circulatory system," a good deal worse under Bright's disease (an excess of 33 per cent.). Fortunately for our professional credit, the rubric "alcoholism" is notoriously worthless, else we should have to infer that doctors were 25 per cent. more drunken than all males.

A very interesting tabulation is that of coal miners in seven fields. The Lancashire field showed a great excess, 65 per cent. more than the Nottinghamshire rate. An important contributor to the excess was the accident rate, but this was not the whole explanation, for the Lancashire miners had more than double the phthisis rate of the Nottinghamshire group. The cancer rates of the highest and lowest were almost identical, and in

no coal field was the cancer rate above the standard. The correlation of mortality with the breathing of dust-laden air is again brought out, and a special tabulation shows "the comparative phthisis mortality for the workers in sandstone to be more than three times as great as that for workers either in granite or limestone."

We could easily go on quoting important results, but this is a document which should be consulted at first hand. Possibly, if and when the new school of hygiene comes to birth, candidates for diplomas in public health will be expected to know something of the contents of such official publications. We recently turned over the examination papers set for the D.P.H. of a famous university through a number of years, and failed to discover a single question to answer which any knowledge of the classical English series of reports upon occupational mortality was required.

#### AUSTRALASIAN MEDICAL CONGRESS, 1923.

At the meeting of the Council of the British Medical Association on February 14th the President, Sir William Macowen, accepted the invitation to represent the Association at the Australasian Medical Congress at Melbourne in November, 1923. The Congress, which will be held within the University of Melbourne, will be opened on November 12th and will close on November 17th. The President of the Congress is Mr. G. A. Syme, M.S., F.R.C.S., the honorary treasurer is Dr. C. H. Mollison, and the general secretary Dr. A. L. Kenny, to whom all communications should be addressed at the Medical Society Hall, Brunswick Street South, East Melbourne, Victoria. A cordial invitation has been extended to members of the parent Association to be present at the Congress. Every member of a Branch of the British Medical Association in Australia and New Zealand has the right to enrol as a member of the Congress on payment of a fee of two guineas. Legally qualified medical practitioners who are not members of the British Medical Association may be admitted to membership of the Congress on certain conditions. The Intercolonial (later Australasian) Medical Congress was first held in Adelaide in 1886; the Congresses served a highly useful purpose, but the need for a more stable and permanent constitution and for a stronger link with the body representing the medico-political interests of the profession has become increasingly evident. The forthcoming Congress is the first to be held under the direction of the Federal Committee of the British Medical Association in Australia. As already announced, the scientific work of the meeting will be organized in twelve sections, and it is intended that the dominant note of the Congress shall be that of prevention; clinicians, investigators, pathologists, and epidemiologists are invited to communicate original work connected directly or indirectly with prevention of disease and with preservation of the health of the Australasian community.

#### THE CENTENARY OF PASTEUR.

ALL members of the profession are invited to attend the social evening at the Royal Society of Medicine on Wednesday next, February 28th, when the centenary of the birth of Pasteur (he was born on December 27th, 1822) will be celebrated. The President of the Society, Sir William Hale-White, will give an address on Pasteur in relation to medicine, and Professor T. M. Lowry, one of the greatest authorities on crystallography (the subject in which Pasteur won his first laurels), will speak on Pasteur's relation to chemistry. He will be followed by Dr. Gustave Monod, who is attending as the representative of the Faculty of Medicine of Paris. He will give a short address on Pasteur as an artist, and will illustrate his remarks by some lantern slides of the pastel portraits drawn by Pasteur himself in early youth. He will also show a collection of some twenty other portraits by Pasteur. There will be a number of other exhibits and an

antograph letter addressed by Pasteur to Professor Miller in 1857, asking him to take an interest in the dispute as to the value of the researches on which Pasteur was then engaged.

#### INSULIN.

LAST November (BRITISH MEDICAL JOURNAL, November 18th, p. 991) the Medical Research Council issued a statement explaining the steps which were being taken in this country for making insulin available as rapidly as possible for the treatment of diabetic patients, under suitable guarantees of authenticity, potency, and safety. At that time the methods of producing this substance were imperfect and necessarily wasteful, and its use in the treatment of disease was, and indeed is still, in the experimental stage. The Council now announces that since then rapid and satisfactory progress has been made as a result of research work which has been undertaken at various centres in this country in confirmation or extension of that already accomplished in the University of Toronto. Members of the Council's scientific staff at the National Institute for Medical Research, Hampstead, have sought to increase the yield of product from the raw material, to simplify, shorten, and cheapen the processes of its production, to obtain accurate measurements of potency by reference to a fixed standard of value, and finally, to find the best methods of securing the bacteriological sterility of the final product. In all these directions important progress has been made. Those working for the Council have been in constant communication with the workers at Toronto, and have both received and given full information of new developments and improvements as they have occurred. The results obtained have been made freely available for the assistance of those engaged in the other work to be mentioned below. Technical information and small samples of the finished product have so far as possible been put at the disposal of approved scientific workers undertaking collateral lines of investigation elsewhere. At various hospitals where the necessary facilities existed for biological and chemical work in the laboratories and for scientific clinical studies, investigation and carefully controlled treatment under suitable safeguards has been undertaken in close association with the work of the National Institute. Insulin is being produced, standardized, and used in treatment for the relief of patients selected for the purpose, at St. Bartholomew's, Guy's, St. Thomas's, the London, and University College Hospitals, in London; in Sheffield, at the University Departments of Pharmacology and Physiology and the Royal Infirmary; and in Edinburgh, at the Royal Infirmary. Arrangements are being made to extend this work to other hospitals and institutions, where the necessary conditions, both personal and material, can be provided. The Council has also made every effort to accelerate the production of insulin upon a manufacturing scale. Experience in Canada and the United States has already shown the difficulty of passing from the small laboratory scale of production to large scale production by mechanical means, without which the product can never become generally available at reasonable cost. The Council has been in communication throughout with certain manufacturing firms in the several parts of the country with whom it has entered into agreements securing in the public interest a control of the safety and potency of the product and its sale at a fair price. The Council has at the same time given every assistance at its disposal by way of information likely to accelerate satisfactory production. In the promotion of manufacture by particular firms it has been necessary to consider the distribution of the available raw material and the special technical difficulties attending its collection and proper use. No royalties are payable to the Council under any of these agreements. The progress towards successful large scale production has been more rapid than the Council had ventured last November to hope. This has been due equally to the laboratory investigations at the National Institute already mentioned and to the experience, skill, and enthusiasm which the firms have shown

in their co-operation with the Council. The Council believes that, subject to limitations of raw material in particular districts, successful manufacture is now assured; but a period of some weeks must pass before laboratory tests and clinical use under special safeguards will have made it justifiable for a supply to be issued generally for routine use under the ordinary conditions of medical practice.

#### THE ANATOMICAL DELINEATIONS OF VESALIUS.

THE Vicary Lecture for 1922, the fourth of the series, was delivered by Mr. W. G. Spencer before the Royal College of Surgeons of England last December; it has been published in the *British Journal of Surgery*, with some well produced illustrations taken from the wood blocks in Vesalius's "Fabrica," and in the copy of the "Epitome" on vellum preserved in the library of the British Museum. The lecture, instituted in 1919 by the Barbers' Company of London, commemorated the fusion with the Guild of Surgeons, upon which ensued the making of special provision for instruction in anatomy of the members of the united company. Vicary, who was sergeant-surgeon to King Henry VIII, was four times president of the united Company of Barbers and Surgeons, and it was to him that Henry VIII handed the Act of Incorporation, as depicted in the famous painting by Holbein. He died in 1561, having continued in the office of sergeant-surgeon under Edward VI, Mary, and Elizabeth. In 1554 he was appointed surgeon to Philip II, to whom also Vesalius, for very different reasons, was surgeon at the same time. The celebration in 1914 of the quadricentenary of the birth of Vesalius was interrupted by the outbreak of war, but in May last year the foundation of the University of Padua, where Vesalius taught while composing his books, was commemorated. The great Italian artists aimed to reach the height attained by the Greeks, and before the time of Vesalius had pursued to some extent the study of anatomy by dissecting the human body. Anatomy owes much to them, for their influence helped to break down the objection to permitting the examination of the human body after death; gradually the prejudice yielded to the influence of reason, and Vesalius placed upon the monument on which the second skeleton figure leans the inscription, "Man's spirit lives, all else death's hand shall claim." Vesalius wrote an epigram describing the difficulties he had to overcome, and it has been turned into English—apparently for the first time—by Miss Joyce Lowe. Mr. Spencer considered it beyond doubt that all the illustrations in Vesalius's book were from his own designs, though the names of the draughtsmen or engravers were nowhere definitely mentioned. The frontispiece, the portrait, and the vignettes give expression to the idea Vesalius had of the way anatomical instruction should be given. The drawings of the nude figures, of the muscles, and of the skeleton all disclosed the same purpose, which was to represent the living body in active movement. Vesalius had a wider aim than to instruct students of medicine and art alone; he thought every educated man should possess a knowledge of anatomy and physiology, as he indicated in the letter dedicating the "Epitome" to Prince Philip: "You will think it base and unworthy that, while such varied courses of study are pursued, the composition of the body which accompanies us through life should be a secret from us; that man should be absolutely unknown to himself; and that we do not examine the construction of the organs formed so perfectly by the Almighty Designer of the Universe. The vital activities of these organs by which everything is accomplished we confine ourselves merely to wondering at." The drawings representing horizontal sections through the human brain were, Mr. Spencer said, of peculiar interest, because it could be demonstrated that the artist had before his eyes the anatomical preparations and drew what he saw; and further, that the sections were made in series from the same brain. The diagrams of nerve, and brain, and artery included in the "Epitome" were intended to be cut out and superimposed upon the nude female and other figures. This Mr. Spencer

made plain to his audience by placing the corresponding lantern slide one over the other in the epidiascope. These diagrams; it was pointed out, were closely related to the *Tabulae Ercellianae* preserved in the College Museum. Before the introduction of methods of preserving anatomical material from putrefaction, and of injecting blood vessels, nerves and blood vessels were dissected out and spread on boards for inspection and drawing: after being varnished over they could be preserved. Evelyn's account shows that a century after Vesalius, his successor in the chair of anatomy at Padua, Vesling, supervised the preparation for Evelyn of human nerves and blood vessels by the same method as had been adopted by Vesalius when preparing his diagrams. Mr. Spencer exhibited copies of all the "Works" of Vesalius from the libraries of the College of Surgeons, the College of Physicians, the Medical Society, and the Royal Society of Medicine.

### THE WAGES OF RESEARCH.

THE gift of Sir Alfred Yarrow to the Royal Society, splendid as it is in amount—£100,000—is made the more valuable by the purpose, conditions, and motives disclosed in his letter to the President. The purpose is to mark the giver's sense of the value of research to the community. The conditions display a wise appreciation of the ever-changing circumstances of scientific inquiry and the impolicy of tying the hands of the Society in the future. The chief conditions are that the fund shall be administered for the Society with unfettered discretion "by the best people from time to time available," care being taken that a gift from the fund shall never lessen any Government grant, and that the rules for the guidance of the committee which will administer the fund shall be reconsidered by the council every tenth year, so that they shall be constantly in accord with the needs of the day. Finally, Sir Alfred Yarrow shows his motive in the following sentence: "I should prefer that the money be used to aid scientific workers by adequate payment, and by the supply of apparatus or other facilities, rather than to erect costly buildings, because large sums of money are sometimes spent on buildings without adequate endowment, and the investigators are embarrassed by financial anxieties." This displays a true understanding of an unfortunate state of things, which has been greatly aggravated by the change in monetary values due to the war. The salaries received even by men who have lived long enough to win the highest distinction in science and who are, by reason of years, approaching the end of their active career, are often disgracefully small, so that they continue throughout their lives to be embarrassed by financial anxieties. Splendid laboratory buildings and a starved staff are no credit to a university and a reproach to the people of this country. In concluding his letter Sir Alfred Yarrow records his "firm conviction that a patriotic citizen cannot give money, or leave it at his death, to better advantage than towards the development of science," and the manner in which he wishes his gift to be used may well be an example to those rich men who may contemplate following his advice.

### THE ENERGETICS OF MUSCLE.

IN his Friday evening discourse to the Royal Institution, Professor A. V. Hill, F.R.S., gave a very striking account of the efficiency and economy of the master tissue of the body. He regarded the activity of muscle, seen in its highest skill and co-ordination in the gymnast or the first-class mechanic, as presenting a scarcely less wonderful picture than that presented by the purely intellectual processes. He began by remarking on the extreme rapidity of some of the voluntary muscular movements. The wing of the wild duck, for instance, beats nine times a second, and that of the sparrow thirteen times, and these rates are far out-distanced, of course, by the vibrations of the wings of insects. Compared with most machines, muscle was an efficient mechanism; it was more efficient than the steam engine for movements of moderate speed, but when forced over a long period it became wasteful. The true function of

muscle was to pass from one state of stress to another, and only incidentally to perform work. The ready recovery from the extreme fatigue consequent upon violent athletic exercises was rightly attributed to the circulation; if the circulation were hindered by a cramped position recovery would be greatly delayed, and in the laboratory, if the isolated muscle were deprived of oxygen, it might show no sign of recovery at all. The heat given out by muscles in activity was measurable by thermo-electrical methods, although in a single twitch the rise of temperature was of the order only of a two-thousandth or a three-thousandth of a degree. If the fatigue record, as shown by the deflection of a galvanometer, were analysed carefully it would be found that the delayed heat produced after the contraction was over might be one and a half times as great as that produced during the actual contraction. This delayed heat was connected with the recovery process. When the muscle contracted it was in a state of stress, and consequently in a state of potential energy, and when relaxed it might be expected that this energy would be released and dissipated in the form of heat. During recovery a portion of the lactic acid which had been liberated during contraction was oxidized and the rest was restored to the glycogen from which it came. In very severe muscular exercise, such as that of a man running a hundred yards at top speed, every muscle fibre in the body was strained to the utmost, and the effort was followed immediately and probably for a considerable time by panting, owing to the oxygen demand. The possibility of continuing a violent exercise for any length of time depended upon the extent of the oxygen "credit" upon which the body could draw. Certain tests which he had carried out at Manchester showed that an individual, after 1½ minutes of violent exercise, required as much oxygen to enable him to recover his equilibrium as he would ordinarily use in one hour when lying at rest. The limit of muscular activity which the body could reach depended upon the maximum rate at which it could obtain oxygen, and this maximum in its turn depended upon various factors. The amount of oxygen which the blood could carry was comparatively small—not more than one-fifth of the blood volume in any case, and probably in ordinary exercises not more than one-seventh. The efficient carriage of oxygen around the body depended very largely upon the lungs as well as upon the heart, and also upon a balance struck between the two. Professor Hill described how he had found that the maximum amount of oxygen he could take into the body was 4.2 litres a minute, and the amount for which he could obtain "credit" during severe exercise was 13 litres. Therefore he was able to run for one minute at a rate governed by 17.2 litres of oxygen, but for the second minute the total oxygen intake would be increased only to 21.4 litres, averaging 10.7 a minute. If it was possible to economize the energy required for a given series of muscular movements then less oxygen would be necessary. It seemed to him probable that the difference between the good long-distance runner and the poor one was not due to the more effective mechanism of the former for supplying himself with oxygen, but rather to the fact that he had learned to use his muscles more efficiently, and therefore more economically; he had acquired the habit of not using inappropriate muscles, or appropriate muscles in an inappropriate rhythm. It was this, rather than capacity for oxygen intake, which was the secret of athletic prowess.

### THE PSYCHOLOGICAL CONDITIONS FOUND IN CRIMINALS.

AT the last meeting of the Birmingham District Medical Women's Association Dr. M. Hamblin Smith, medical officer of Birmingham Prison, and the author of an important work published last year on the *Psychology of the Criminal*, gave a lecture with that title. He, however, began by remarking that a better title would be "Some of the psychological conditions found in offenders," since the idea that there was a definite criminal class sharply differentiated from other

classes was no longer held. He laid down the preliminary principle that criminal conduct, like all other forms of conduct, is caused by the mental content. Certain forms of physical defect might affect the sufferer's mentality, and so might become predisposing causes of criminality. The differences in the estimates made of the proportion of mental deficiencies to be found among delinquents were amazing and were due to diverging views as to the standard of comparison adopted by the examiner. He entered at some length into his objections to the German scale for the measurement of intelligence, and described his own scheme of tests. Having discussed the conception of "moral imbecility" and rejected it, he proceeded to discuss the influence which the hypothesis of the unconscious mind has had upon the conceptions of delinquency, stating that, on a most cautious estimate, the proportion of offences due to mental conflict was at least 10 per cent. A discussion of mental conflict and of the various methods of discovering its presence followed. Dr. Hamblin Smith expressed the opinion that views on this subject will be affected by the acceptance or rejection of the doctrine of scientific determinism. He illustrated the importance of these conflicts by the example of the chronic alcoholicist problem. He also briefly considered those cases of delinquency which are due to social maladjustment and to "current conflicts" set up by environmental conditions, and the mental states which are known, for want of a better word, as "psychopathic." In conclusion, he described the special arrangements made at Birmingham prison for the examination of cases suspected of mental abnormality, and pleaded for further study of these questions by his audience, so that, having understood the subject themselves, they might take their part in the education of public opinion.

#### TREATMENT OF EARLY MENTAL DISORDER.

THE treatment of early or incipient mental disorder is a matter that has engaged a great deal of attention during the past few years, and has frequently been discussed from various points of view in our columns. Several efforts have been made to initiate legislation to deal with it; one of them was Clause 10 in Part 2 of the ill-fated Ministry of Health (Miscellaneous Provisions) Bill introduced by Dr. Addison in August, 1920. A memorandum on the bill, issued soon afterwards by the Ministry, contained the following statement: "The importance of early treatment of these cases, wholly dissociated from the machinery of the Lunacy Acts, is now generally recognized." Before the dissolution of the late Parliament it was understood that Sir Alfred Mond had under consideration the draft of a bill to enable persons suffering from incipient mental disorder to be treated in public or private mental hospitals without certification. One aspect of the problem is touched on by Dr. B. H. Shaw, Medical Superintendent of the Staffordshire County Mental Hospital, in his last annual report. "Before a patient suffering from nervous breakdown becomes legally certifiable, whatever the cause may be, it is obvious," he says (p. 10), "that, from the standpoint of future complete recovery, efficient treatment, involving in most cases complete detachment from home surroundings, should be taken in hand as early as possible. In order to effect this it is in the first place necessary that the patient should come under the notice of his or her local medical man for some considerable time before certification becomes necessary." In order to estimate the number of such cases in which the medical practitioner in attendance had sufficient opportunity of observing the patient in an early stage of mental breakdown Dr. Shaw went carefully into the histories of all the first attack cases admitted under his care during 1921. Of the 73 women and 76 men the vast majority were considered certifiable by their doctor at his first attendance. Twelve of the men and 21 of the women were seen by their doctor for the first time more than three weeks before admission. Of these, 5 men and 4 women, owing to their condition, would not have benefited by any form of early treatment. Thus the number of cases

likely to be dealt with as incipient was reduced to 7 men and 17 women, making 9.3 per cent. of first attack cases in men and 21.8 per cent. in women. "On further examination of these cases," Dr. Shaw continues, "I have come to the conclusion that about 4 per cent. of the men might probably have been dealt with efficiently under some different scheme without the necessity of certification, and about 6 per cent. of the women. I am inclined to think that these numbers even are excessive, and there is little doubt, therefore, that any scheme for dealing with incipient insanity would be greatly handicapped by the fact that medical men in general practice do not themselves get the opportunity of seeing these cases early enough for efficient treatment." This expression of opinion from an experienced medical superintendent seems worthy of quotation. The history of the British Medical Association's efforts to promote legislation for the better treatment of early mental disorder was told in our columns as lately as July 8th, 1922 (p. 51).

#### MEDICAL MUSEUMS.

THE International Association of Medical Museums has begun the publication of a *Journal of Technical Methods*, to replace the series of bulletins, of which seven have been published. The first number is a memorial to Sir William Osler, who was one of the earliest members of the Association and always took a great interest in its work. Meetings are held from time to time for the discussion of technical matters connected with the upkeep of medical museums. The communications to the present number are either retrospects of technical subjects by experts or short contributions of an essentially practical nature. As examples of the general reviews we may mention articles on histological technique used in pathology, preserving fluids for gross pathological specimens, and a discussion on photomicrography. There are seven articles on war museums, seven articles on colour preservation and mounting, three on methods of making and labelling museum jars, an article on museum arrangement, three articles on photography, six on microscopic technique, and three on bacteriological technique. In addition five communications on comparative and morbid anatomy are published, together with articles on parasitology, cardiac anomalies, and monstrosities, and abstracts of current literature on microscope technique. This Association conducts an "experience department," and members are invited to forward to this department requests for information they may desire on any subject that falls within the range of this bulletin, such as museum or microscope technique, museum classification or arrangement. Another function of this Association is the development of an international system of exchange of museum specimens and pathological material for microscopic research, and the bulletin advertises what is "wanted" and what is "offered" by curators of museums in different parts of the world.

#### PROFESSIONAL SLANG.

A CORRESPONDENT this week protests against the use of the abbreviations "T.B.," "T.b.," and "t.b." He asserts that this reprehensible practice is becoming more common, and our own experience confirms him. Such terms are used, no doubt, to save the writer trouble, without regard to the comfort of his readers. One of Dr. Weatherhead's examples, "T.B. of lungs. . . T.B. not found in sputum," illustrates one of the evils of the practice, for in this instance "T.B." seems to be used in two senses—in the first place for tuberculosis, and in the second for tubercle bacilli. But the evil extends much beyond this. We often receive papers scattered through with contractions or initials which the author does not explain; some of them no doubt are commonly understood; others are known in laboratories, sometimes only in particular laboratories. Sometimes laboratory workers seem to use them without taking the trouble to ascertain how they should be defined; they have

become mere symbols, and as neither physiology nor pathology is a department of algebra their use leads to confusion. Out of consideration for his readers a writer, when first he is tempted in any article to use a slang contraction or set of initials, should be at the pains to give the term in full, following it by the contraction he intends to use later on; he ought to be quite sure also that somebody else has not used the same set of initials to mean something else. Examples of another class of slang which seems to us objectionable are afforded by such phrases as "stained with Giemsa" or "stained with Leishman"; Sir William Leishman is, happily, still with us, and it is horrible to think of his being used as a stain. Another grievance of printers and readers is the carelessness with which the decimal point is used. We saw in print the other day the phrase 535.6 per cent.; it was discovered before it was too late, but this good fortune does not always befall. Recently we had in our own pages a regrettable incident in which the decimal point disappeared altogether. It is always inconvenient to use such a form as .5; the decimal point may be overlooked by the printer or broken during the process of printing. The form should always be 0.5. It is said that language is given to man to conceal his thoughts. The application was to the diplomatists. When a man sits down to write a paper on a scientific subject his object is not to beguile or confuse, but to inform his readers.

#### VENEREAL DISEASE IN THE UNITED STATES.

THE annual report for 1922 issued by the United States Public Health Service contains some interesting facts concerning venereal disease in that country. As in England, there was a notable falling off in the number of new cases applying for treatment. In the Statistical Bulletin of the Metropolitan Life Insurance Company, quoted in the report, it is stated that there has also been a decline of 21 per cent. in the mortality rate due to syphilis amongst policy holders during the last four years, the diminution occurring chiefly in those between the ages of 25 and 55 years. It is suggested that this improvement in the early and middle years of life is the result of increasing effectiveness in the treatment of syphilis. An analysis of the figures for the total number of attendances at clinics indicates that in the United States, as in England, a small percentage only of patients suffering from gonorrhoea appear at the clinics. In 1922 the total number of patients admitted to the clinics for syphilis in the United States was 74,649, and that for gonorrhoea 60,954. As far as can be seen from available data on the subject, the normal ratio of incidence of gonorrhoea to syphilis is at least 5 to 1, and it must, therefore, be assumed that patients suffering from gonorrhoea either treat themselves or else consult private practitioners. A gratifying item in the report is the great increase in the number of persons discharged as non-infectious, the ratio between new patients admitted and those discharged as non-infectious being as high as 42.6. In many of the States of America notification is in force. Statistics show a decrease of 13 per cent. in the number of cases of venereal disease reported in 1922, compared with the number reported in the previous year. This diminution would appear not to be entirely accounted for by the decrease in the incidence of new cases, but in the opinion of the editor of the reports indicates the necessity for more active propaganda amongst general practitioners dealing with these cases. The value of educational measures has been fully recognized in the United States, and grants have been made to facilitate the spreading of knowledge concerning venereal disease amongst the various sections of the public. In addition to pamphlets, propaganda has been carried out by means of lantern slides, cinema films, lectures, and addresses. Intensive work amongst the coloured population has been carried out in most of the Southern States. The obtaining of trustworthy statistics on the subject of venereal disease is, of course, a matter of the greatest difficulty. Progress in the control of these diseases will be measured ultimately by a diminution in the number of infections and in

the control of these infections as they occur. Meanwhile, in order to determine what progress has been made, certain indices have been selected in the United States Reports. These would appear to show that definite progress has been made. The grounds for believing that the measures directed against venereal disease are already meeting with some measure of success are as follows: (1) A reduction in the number of deaths from syphilis. (2) A reduction in the number of cases of venereal disease reported, with an increase in the number of physicians reporting. (3) A decrease in the total amount of venereal disease occurring in penal and public institutions. (4) A decrease in the number of positive Wassermann tests returned from laboratories, together with an increase in the total number of examinations made. (5) A decrease in the number of pelvic operations due to gonococcal infections reported from gynaecological clinics.

#### MEDICINE'S DEBT TO ART.

THE paper on "The debt of medicine to the fine arts" contributed by Dr. J. A. Nixon to the History of Medicine Section of the Royal Society of Medicine was noticed in our issue of December 30th, 1922 (p. 1275). Substantially the same paper formed the subject of Dr. Nixon's presidential address at the opening of the fiftieth session of the Bristol Medico-Chirurgical Society, and it is printed in full, with eleven illustrations, in the January issue of the *Bristol Medico-Chirurgical Journal*. The pictures include anatomical sketches by Leonardo da Vinci and Laurentius Phries; pictures of skeletons by Caspar and Gérard de Lairese, and one attributed to Titian; one of Christopher Wren's plates illustrating Willis's *Cerebri Anatome*; sketches by Sir Charles Bell and Sir James Paget; and a reproduction of the medallion executed by Mr. J. Greig Smith—whose example and writings in abdominal surgery had so great an influence on its development—of Dr. E. Long Fox, physician to the Royal Infirmary, Bristol, and President of the British Medical Association when it met in that city in 1894.

#### CHRISTOPHER WREN BICENTENARY.

THE bicentenary of the death of Sir Christopher Wren is on Sunday, February 25th, and during next week a series of ceremonies and celebrations will be held in London to commemorate the occasion. The ceremonies will be organized by the Sir Christopher Wren Bicentenary Grand Committee, consisting of representatives of thirty eight learned, scientific, and municipal bodies. The Royal College of Physicians (whose Hall, in Warwick Lane, City, was designed by Wren) is represented by Dr. F. G. Dawtrey Drewitt; the Royal Society of Medicine by Sir William Hale-White; and the Royal Society (of which Wren was one of the original members and its President from 1680 to 1682) by Professor H. H. Turner. A sumptuous memorial volume of essays on various aspects of Wren's life and work has been prepared under the auspices of the Grand Committee and the Royal Institute of British Architects; profits from its sale will be devoted to the St. Paul's Cathedral Preservation Fund. The editor is Mr. Rudolf Dircks, Librarian of the Royal Institute of British Architects, and Sir Aston Webb, President of the Royal Academy, contributes an introduction. The publishers are Messrs. Hodder and Stoughton. The book will contain reproductions in colour of Kneller's portrait of Wren in the National Portrait Gallery and of that by Michael Wright in the possession of the Royal Society. It will include also coloured plates by seventeenth and early eighteenth century artists; facsimiles of letters and drawings by Wren; and numerous reproductions of contemporary engravings and drawings. We hope to publish next week some account of this great Englishman and his relation to the progress of science.

#### OXFORD OPHTHALMOLOGICAL CONGRESS.

THE Oxford Ophthalmological Congress will be held at Keble College from July 4th to 6th, with a possible extension to the morning of July 7th, according to the length of the

programme. On July 5th a discussion on the relation of dental sepsis to diseases of the eye will be opened by Mr. W. Lang and Mr. W. R. Ackland. The Doyno Memorial Lecture will be delivered on the morning of July 6th by Dr. H. M. Traquair on the differential characters of scotomata and their interpretation. The official dinner of the Congress will take place in the hall of Keble College on July 5th. The honorary secretary is Dr. Bernard Cridland, Salisbury House, Wolverhampton, who will be glad to receive offers of papers, pathological specimens, and descriptions of new operations.

#### INBORN ERRORS OF METABOLISM.

A course of three lectures, part of a course of advanced lectures in medicine, arranged by the University of London, on recent work on inborn errors of metabolism will be given by Sir Archibald Garrod, K.C.M.G., M.D., F.R.S., Regius Professor of Medicine in the University of Oxford, at the house of the Royal Society of Medicine on Wednesdays, February 28th, March 7th, and March 14th, at 5.30 p.m. on each day. The first lecture will contain a general review of inborn errors of metabolism, the second will deal with alcaptonuria and ochronosis, and the third with haemato-porphyrin congenita (congenital porphyria). The chair will be taken by the Vice-Chancellor of the University, Mr. H. J. Waring, M.S., F.R.C.S. The lectures, which will be illustrated with the epidiascope, will be addressed to advanced students of the University, but members of the profession will be welcomed, and we anticipate that very many will desire to hear the views of an acknowledged master on a subject of extraordinary scientific interest and of no little practical importance.

A CHANGE has been made in the regulations for the examination for the membership of the Royal College of Physicians of London. Hitherto it has been the custom for the President and Consors to grant exemption to candidates over the age of 40 years from the examination in languages and pathology; it has now been decided that on and after October next exemptions shall not be granted solely on the ground of age.

### Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

**Dangerous Drugs (Amendment) Bill.**—The Home Secretary (Mr. Bridgeman), on February 15th, introduced the Dangerous Drugs and Poisons (Amendment) Bill, which is designed to amend the Act of 1920 in certain respects. The text of the measure will be found in the SUPPLEMENT of this week.

**Medical Research Publications.**—Sir H. Nield asked, on February 19th, whether the attention of the Chancellor of the Exchequer had been called to the reports of the Industrial Fatigue Research Board published by the Stationery Office at prices varying from 3s. down to 6d., whether he would examine No. 19 of such publications entitled "Two contributions to the study of accident causation," and whether in view of the excessive burdensome taxation prevailing he would appoint a committee rigorously to cut down expenditure on such publications and confine the operations of permanent officials concerned to matters of an urgent and practical character. Mr. Baldwin replied that the series of publications gave the results of one branch of research work now being carried on by the Medical Research Council with a Parliamentary grant-in-aid of £150,000 per annum. In view of the magnitude of national expenditure resulting directly and indirectly from disease and the vital importance of all measures calculated to improve the health and efficiency of the industrial population, he could not regard this amount as excessive, and he thought that its detailed allocation might with advantage be left to the discretion of the Council. In their researches on industrial fatigue the Council were advised by a board, composed like itself mainly of eminent scientific and business men. Considerable value was attached to the work in the industrial world. The reports are issued at a price calculated to cover the cost of printing and publication.

**Indian Medical Service.**—Sir J. Hewett asked, on February 19th, what were the terms on which some thirty officers were recently recruited for the Indian Medical Service. Earl Winterton replied that the terms offered, in addition to the ordinary conditions of permanent service in the I.M.S., were a gratuity of £1,000 and free return passages for officers who might wish to leave the service at the end of five years. A similar gratuity was admissible to Royal

Army Medical Corps officers after a somewhat longer period of service. The offer was necessitated by the serious shortage of European officers in the service, resulting from a failure in the supply of candidates since the outbreak of war.

**Inspection of Morphine Factories.**—Replying to Lord Robert Cecil on February 19th, Mr. Bridgeman said that morphine factories were subject to inspection by Home Office inspectors. Manufacturers were required to keep detailed records and make periodical returns of their purchases of the raw material, their production of the drug, and their sales, and a licence had to be obtained for each consignment of the drug exported from this country. The Home Office was doing all in its power to check the abuses of the drug traffic, but until full international co-operation had been secured it would be impossible to prevent them altogether.

**Medical Retrenchments at Kenya.**—In reply to Mr. Short, on February 20th, Mr. Ormsby-Gore (Under Secretary for the Colonies) said that the retrenchments in the Medical Department of Kenya, involving the abolition of one post of senior medical officer, eight of medical officers, one of dental surgeon, and a number of other appointments, had been framed so as to affect as little as possible the principal centres of population. They concerned mainly the minor stations and those outstations where minor facilities existed or might be made available for medical attention. The reductions had been effected with great reluctance, but the principal medical officer was satisfied that efficiency could be maintained. Four nurses were affected.

**The Pensions Services.**—An amendment to the Address, moved by Mr. Adamson for the Labour party, to call for a Select Committee of Inquiry into the pensions services, was, on February 20th, defeated by 307 votes to 176, after a vigorous defence by Major Tryon, to which we shall recur next week.

**National Insurance.**—Sir W. Joynson-Hicks, on February 15th, gave, by request, the following figures as to National Insurance in England and Wales for the year 1921:

Amount paid from all sources under the National Health Insurance Acts	£35,356,000
Amount disbursed for benefits (including sickness benefit)	£7,200,000
Amount disbursed in administration	21,562,000
	4,817,000

**Medical Reassessment.**—Major Tryon, on February 15th, assured Mr. F. Roberts that any man whose disablement had been assessed by the Pensions Department at less than 20 per cent. could appeal to a medical appeal board, and if and when the award was made final, to the independent assessment appeal tribunal. Mr. Roberts had put it that men in the lower category were disadvantaged.

**Ex-service Men in Asylums.**—Replying to Mr. Lansbury and Mr. F. Roberts, on February 15th, Major Tryon said that the number of ex-service men in asylums, for whom the temporary responsibility of the Pensions Ministry had ended, was 750. Some of these cases were still under consideration by appeal tribunals and otherwise, and the figure he had given might still be somewhat reduced. All cases of the class in question had received the most careful and sympathetic consideration, both by the medical officers of his Department and by the appeal tribunals, with a view, if possible, to continuing their previous benefits consistently with the provision of the Pension Warrants. But he was not prepared to accept the suggestion that the Ministry should be permanently responsible for these or any other ex-service men whose disabilities were not connected with their war service.

**Artificial Limbs.**—Lieut.-Colonel Guinness (Under Secretary for War) stated, on February 15th, in answer to Major Cohen, that non-commissioned officers and men requiring artificial limbs were being dealt with by the Commissioners of the Royal Hospital, Chelsea. He had no reason to suppose that the best expert services were not available under the present system, but he would consider the suggestion that these men should, in future, be sent to the Ministry of Pensions' Limb-Fitting Centres.

**Special Diet.**—The average number of ex-service men who received special diet during the last six months of 1922 was, according to Major Tryon, about 165, of whom nearly 95 per cent. were cases of pulmonary tuberculosis. In addition, during the last few months, an average of about 2,600 pensioners suffering from pulmonary tuberculosis had been in-patients in institutions and sanatoriums where they received, at the cost of the Ministry, any special diet medically recommended. Major Tryon stated, on February 15th, that special diet is limited to men suffering from pulmonary tuberculosis and diabetes mellitus.

**The Dogs Bill.**—Sir Frederick Banbury, on February 16th, introduced his bill "to prohibit the vivisection of dogs." Following on the lines of the measure which he has brought forward from year to year, the bill lays down that "it shall be unlawful to perform any experiment of a nature calculated to give pain or disease to any dog for any purpose whatsoever, either with or without anaesthetics, and no person or place shall be licensed for the purpose of performing any such experiments." The penalties clause provides that any person performing, or assisting, or taking part in performing any such experiments as those to which the bill refers shall be guilty of an offence against the principal Act and punishable accordingly. Sir Frederick Banbury, not having been fortunate in the ballot for first places for private members' bills at Friday sittings, has put down this measure on the second Order for Friday, March 2nd, for second reading.

## THE HUNTERIAN FESTIVAL IN LONDON.

THE Hunterian Festival of the Royal College of Surgeons of England was marked this year by the delivery of Sir JOHN BLAND-SUTTON'S Hunterian Oration, published last week (p. 267), and by a dinner in the evening, at which Mr. RUDYARD KIPLING proposed the Orator's health.

The President, Sir ANTHONY BOWLEY, was in the chair at the dinner, which was held in the library; among the guests were the Lord Chancellor, the Lord Mayor of London, the President of the Royal Society, the President of the Royal College of Physicians, the President (Sir William Macowen), and the Chairman of Council (Dr. R. A. Bolam) of the British Medical Association, the President of the Royal Academy, the Master of the Temple, the Treasurers of Lincoln's Inn and Gray's Inn, and the Masters of several City Companies.

After the usual loyal toasts, the memory of John Hunter was celebrated in silence.

The President then gave the toast of the visitors, coupling it with the name of the Lord Chancellor, Viscount Cave, to whose work as Chairman of the Committee on Voluntary Hospitals he paid a tribute, describing its report as the second charter of voluntary hospitals in this country.

Viscount CAVE said that he became Chairman of the Voluntary Hospitals Committee with an open mind. The effect of the evidence as it was given day by day, week by week, was to breed in him deep admiration for, and a sense of real gratitude to, those who, whether as Governors or medical men, had, in spite of discouragement and criticism, kept flying the flag of the voluntary hospital system. The Committee had before it evidence from many countries, and there was impressed on his mind the contrast between the position of the patient in a hospital in this country, cared for by a capable medical staff and attended to by trained nurses, and that of a patient in some State hospitals abroad, where the sick person went in and was hardly heard of again until he came out either head foremost or feet foremost. The evidence the Committee received made him more thankful than he could well express that the genius of our English-speaking race had evolved a system which ensured the happiness and the continued health of millions of our fellow countrymen.

Mr. RUDYARD KIPLING then gave the toast of the health of the Hunterian Orator. Beginning by a reference to the Orator's quotation from Ecclesiasticus, he said that there was an alternative reading, which ran "Honour a physician before thou hast need of him"; but it was seemly to honour him after that event. (It will be remembered that Mr. Kipling is convalescing from an operation he recently underwent.) He claimed to have another excuse for speaking in such an assembly, for he was a dealer in words—the most powerful drug used by mankind. Not only did words infect, narcotize, and paralyse, but they entered into and coloured the minutest cells of the brain, very much as madder mixed with a stag's food coloured the growth of the antlers; and in man the acquired tint was transmissible. There was, he continued, a legend which had been transmitted to us from the remotest ages, and had entered into many brains and coloured not a few creeds:—

It is this: Once upon a time, or rather, at the very birth of time, when the Gods were so new that they had no names, and Man was still damp from the clay of the pit whence he had been digged, Man claimed that he, too, was in some sort a deity. The Gods weighed his evidence and decided that Man's claim was good—that he was, in effect, a divinity, and, as such, entitled to be freed from the trammels of mere brute instinct, to enjoy the consequence of his own acts. But the Gods sell everything at a price. Having conceded Man's claim, they came by stealth and stole away this godhead, with intent to hide it where Man should never find it again. But this was none so easy. If they hid it anywhere on Earth, Man, the inveterate hunter—the father of all hunters—would leave no stone unturned or wave unplumbed till he had recovered it. If they concealed it among themselves, they feared that Man might in the end batter his way up even to the skies. And, while they were all thus at a stand, the wisest of the Gods, who afterwards became the God Brahm, said, "I know. Give it to me!" And he closed his hand upon the tiny unstable light of Man's stolen godhead, and when that great hand opened again the light was gone. "All is well," said Brahm. "I have hidden it where Man will never dream of looking for it. I have hidden it inside Man himself." "Yes, but whereabouts inside Man have you hidden it?" all the

other Gods asked. "Ah," said Brahm, "that is my secret, and always will be unless and until Man discovers it for himself."

Thus, then, does the case stand with Man up to the present. Consider, for a moment, the pathos of the poor brute's position. You all know the common formula for him, "Born of Woman, on Woman designed to beget his like—the natural quarry of the Seven Deadly Sins, but the Altar of an inextinguishable Hope." Or, more scientifically (I regret I am not a scientific person), he might be defined as "An imperfectly denatured animal intermittently subject to the unpredictable reactions of an unlocated spiritual area."

It is just this search for this unlocated spiritual area, whether it be a growth or a survival, which has preoccupied Man from that day to this. The Priest and the Lawgiver have probed and fished for it all through the ages; but, more than any other, through all the ages, the Leech, the Medicine-Man, the Healer, has been hottest on its track. He has searched, wherever he dared—openly or furtively—in safety or at the risk of his life. In the early days the Astrologer-Physician, as he called himself, dreamed that the secret of Man's eternal unrest was laid up in the sun, moon, and stars; and consequently, since all created things were one in essence, that a universal medicament for Man's eternal woes would be discovered upon earth. So he searched the earth and the Heavens for those twin secrets, and sacrificed himself in the search as a matter of course. Later, when the embargoes on the healing art were lifted, when, at last, he was permitted to look openly into the bodies of mankind, the nature of his dreams changed for a while. He had found more wonders beneath his knife than earth or the planets had heretofore shown him. And that was barely ten generations ago. Once again, the Surgeon, as he had become, renewed his search, and once again sacrificed himself in the search as his passion drove him. There is no anaesthesia so complete as man's absorption in his own job.

In the teeth of the outrageous, the absurd disabilities imposed on him, Man, the imperfectly denatured animal, who cannot trust the evidence of his own senses in the simplest matter of fact; whose evidence on the simplest matter is coloured by his own iniquities; Man, always the hunter, went up against the darkness that cloaked him and every act of his being, to find out what order of created being he might be. He called it scientific research. It was the old quest under a new name. But, this time, the seekers who headed it, unlike the Priest and the Lawyer, admitted that they knew very little. Experience had taught them to be humble. For that reason their knowledge was increased. They moved forward into areas of the body, which, till then, had denied themselves to man's hand. They were bewildered by mysteries which some new marriage of observation upon accident, some predestined slip of the knife resolved into—mysteries profounder still! Is it any wonder that the old dreams came back? The dream of the essential unity of all created things—the dream that some day that which men called life might be led into matter which men called dead—the boldest dream of all, that eventually Man might surprise the ultimate secret of his being where Brahm had hidden it, in the body of Man. And, meanwhile, their days were filled, as yours are filled, with the piteous procession of men and women begging for leave to be allowed to live a little longer, upon whatever terms.

Is it any wonder, gentlemen of the College of Surgeons, that your calling should exact the utmost that man can give—full knowledge, exquisite judgement, and skill in the highest, to be put forth, not at any self-chosen moment, but dully at the need of others? More than this. Your dread art demands the instant, impersonal vision which in one breath, one beat of the pulse, can automatically dismiss every preconceived idea and impression, and as automatically recognize, accept, and overcome whatever of new and unsuspected menace may have slid into the light beneath your steadfast hand.

Such virtue, Mr. Kipling concluded, was not reached or maintained except by a life's labour, a life's single-minded devotion. Its reward was not only the knowledge of mastery and the gratitude of the layman. Its true reward was the dearly prized, because unpurchasable, acknowledgement of one's fellow craftsmen.

Sir JOHN BLAND-SUTTON, in response, said that he had studied animals all his life, though his chief concern was with man, the greatest animal because he possessed brains. Meanwhile Mr. Kipling had been studying the psychology of animals, like Hunter before him, but Hunter had no faculty of expression. The psychology of animals was mixed up not only with the religion of Brahm, Buddhism, but with every religion, as witnessed by the story of Balaam and the ass, Jonah and the whale, and Tobias and his dog. The

*Jungle Book*, one result of Mr. Kipling's study of the psychology of animals, would go down to future generations along with the story of Beauty and the Beast, Red Riding Hood and the wolf, and many others, because they were really studies of the animals themselves related beautifully, simply, and artistically by a real genius. Men of the stamp of Hunter and Kipling did great good in the world because they inspired others. Without this power no man attained permanence. Men very rarely spoke well of their friends in their presence, except in after-dinner speeches, and John Hunter was not appreciated by his contemporaries. The great work Hunter did was the collection of the specimens now safeguarded in the College, but the spirit of Hunter was a quickening influence on the surgeons of to-day.

## England and Wales.

### MANCHESTER: DR. NIVEN'S FINAL REPORT.

In his report on the health of the city of Manchester for 1921 Dr. James Niven brings to a conclusion the long series of classic reports which he has presented to the Manchester Corporation during the twenty-seven years he has held the position of medical officer of health for that city. The issue of the report affords an opportunity for comparing the present-day conditions of a large rapidly growing industrial centre with those which existed a quarter of a century ago and of emphasizing the contention that there is no more important duty cast upon a local governing body than that which is concerned with the health of the community. How an enlightened local authority, guided by the wise counsel of a skilled adviser, has accomplished that duty is shown on almost every page of Dr. Niven's report.

When Dr. Niven succeeded Dr. J. F. W. Tatham as medical officer of health for Manchester he brought with him considerable administrative experience gained as medical officer of health for the neighbouring town of Oldham, where the sanitary conditions were somewhat similar to those in Manchester, though the population was only about 150,000, whereas in Manchester it was 500,000, and has since increased to 750,000. A mere comparison of statistics in the intervening years is a remarkable revelation. In 1895 the birth rate was 33 per 1,000 of the population; in 1921 it had dropped to 24 per 1,000. The actual number of births in the two years—about 17,000—was practically identical; but whereas in 1895 only 14,000 survived twelve months, in 1921 nearly 16,000 were living at the end of their first year. Expressed in another way, the infant mortality rate fell from 202 per 1,000 births to 97. In Dr. Niven's opinion this is largely due to the long-continued education of mothers by the health visitors, the maternity and child welfare centres, the schools for mothers, and the school medical officer with his staff. The actual number of deaths in 1895 was 13,000, and in 1921 it was 10,000, giving death rates respectively of 24.5 and 13.6 per 1,000. The saving of lives thus compensated to some extent the fewer births.

In these days when water carriage is almost universal in large towns it is difficult to believe that only five-and-twenty years ago Manchester, with its population of half a million, was on the conservancy system. In the business premises in the centre of the city there were water closets, but elsewhere privy middens and pail closets abounded. The walls of the privies were pervious and many of them adjoined houses, and the pail closets were defective to a remarkable degree. The pail contents was carted to a central dépôt and sent away in its crude state as nightsoil to farmers in Cheshire. In one of his earliest reports, after stating that the vital statistics for the year did not offer much subject for congratulation, Dr. Niven wrote that when these came to be discussed in detail, in the light of a knowledge of the individual cases of fever, and of the conditions of excreta collection and removal, an accumulation of indications presented themselves pointing to those conditions as operating decidedly in the production of a high death rate. Again and again he reiterated his condemnation of the conservancy system, and in the early years of the present century a determined effort was made by the corporation to abolish it in favour of water carriage. So successful have those efforts been that nearly 86,000 pail closets and privies have been abolished in the past thirty years, and the number still in use is almost negligible. During this period the death rate from typhoid fever fell

from 0.24 per 1,000 persons living to 0.02 and that from diarrhoeal diseases from 1.19 per 1,000 to 0.52.

In his report for 1895 Dr. Niven wrote: "As a result of the knowledge which has accumulated during the last thirty years no well informed man now doubts that tuberculosis is an infectious disease." He then proceeded to put forward his views as to the preventive measures which should be adopted, placing foremost the notification of cases to the medical officer of health. At the end of 1899 a voluntary system of notification came into force in Manchester, with the result that about 1,500 cases were notified each year until 1912, when notification became compulsory. In 1921 there were notified 1,611 cases of pulmonary and 577 of non-pulmonary tuberculosis. An indication of the extent of the preventive measures in operation may be gathered from the fact that there are now engaged in carrying them out three whole-time medical officers and four part-time consultants, in addition to a staff of fourteen investigation officers and tuberculosis nurses and twenty clerks. The corporation established the Baguley sanatorium, where there are 318 beds available for adult cases at all stages of the disease, the majority of cases being of an advanced type. For early cases of pulmonary tubercle in adults, and for surgical tubercle in children, the Abergele sanatorium, with fifty-six beds, is available.

Many of the activities of the Manchester Public Health Department recorded in the report for 1921 find no place in the reports of earlier years. Among them the most important is the scheme for the treatment of venereal diseases which came into being in 1917. There are six centres for treatment at various hospitals, and two early treatment centres are in operation. Dr. Niven expresses the opinion that venereal disease seems to be diminishing, but there appears, he says, a strange reluctance to pursue the policy outlined by the Royal Commission—namely, to treat the disease as a communicable and preventable one.

It must be a source of great satisfaction to Dr. Niven to feel that his labours have borne such abundant fruit. He has benefited not alone the citizens of Manchester but the whole civilized world.

### LONDON'S UNHEALTHY AREAS.

Although in the Orient large cities housing vast populations have been known for many hundreds of years, in the West the mammoth city is a recent growth. So new is the phenomenon of millions of people aggregated in one urban community that we have no word to describe it; "town," "city," "urban county" are altogether inadequate. London, New York, Glasgow have outgrown the connotation of the terms in which they are described. That the greater cities have failed to afford what must be regarded as fundamental requirements of living conditions was demonstrated during the war in a way that has stirred the national determination to put a period to these evils. So large a part of life, especially at the period when physique is being established, is spent in the home that the house ranks among the most important factors determining health. Every medical man knows how lamentably short of essential requirements the slum houses of our great cities fall. The problem of their elimination and replacement by reasonably healthy houses is one of the greatest and most urgent that beset our civic authorities.

Mr. Topham Forrest, superintending architect to the London County Council, in his Chadwick lecture on London's unhealthy areas, naturally dealt with some of the fundamental difficulties of the problem. Not only are there, as Mr. Forrest pointed out, nearly 2,000 recognized unhealthy areas in London, but there are also square miles of streets in which the houses, while not grouping themselves technically as unhealthy areas, are nevertheless in a hygienic sense to a very large extent to be regarded as indistinguishable from such areas. Working-class London within the county was for the most part built before the essentials of house construction, as now understood, were formulated and insisted upon. The result is that large numbers of the population of London inhabit houses which are damp, dark, badly planned and ill arranged, and lacking in one respect or another the elementary requirements of a healthy and convenient home. The problem is complex. Since there are no empty houses or rooms into which the occupants of a congested area may be transferred, the clearance of the area can only be done section by section, and a beginning cannot be made unless a vacant site can be found for an initial block of buildings. Transport difficulties make it impossible to transfer many of the people to districts outside London: most of the bread-

winners work in London, and they would have to be carried to and fro each day; but the suburban trains are during the rush hours packed to their fullest capacity.

Mr. Forrest has not unduly stressed this difficulty. In the days of the jerry-builder, the problem of rehousing as it exists to-day had scarcely arisen. The suburbs absorbed the population of central London as fast as displacement proceeded. But the dormitories of London, as they were called, now pour into business London many times the numbers of people who made their exodus two or three decades ago. A new generation has arisen, and transport is strained to breaking-point. Central residential London can no longer afford the "cottage" type of house so widely and properly desired by the London worker. Mr. Forrest was, therefore, compelled to recommend a type of building of more than three stories for the areas in question. Here, however, certain important facts regarding the angle of the sun's rays in London had to be borne in mind. By means of diagrams he showed that in winter in Paris buildings (facing south) of at least a story higher, and in New York at least four stories higher, could be built without causing any greater obstruction to light than would five-story buildings in London—that is to say, buildings of nine stories in New York and of six stories in Paris would throw shadows no longer than do five-story buildings in London, so that in London buildings cannot be either so high or so close together as in Paris or New York. The law in London permits buildings of five stories to be as near each other as their own height. But this means that the ground floor rooms can only have direct sunlight for something less than six months out of the twelve, and for the greater part of even that period they will not have more than an hour or so a day. The lecturer suggested that in London buildings of, say, 45 ft. high should not be nearer together than 60 ft., and if economic considerations permitted he would prefer that such buildings should be kept away from one another to a distance equal to about twice their height.

If London is to continue manageable it will be by the recognition of fundamental principles such as these. Almost more important than the provision of houses is the insistence upon observance of sound site planning by the authorities dealing with this great problem. The replanning of built-up areas is beset with difficulties, but the best that could befall London at the present time would be a revival of building activity under such a minimum of control as would secure adherence to essential and well recognized principles not only in house planning but in site planning as well.

#### FOREIGN HEALTH OFFICERS IN LONDON.

A party of twenty-five health officers, drawn from Austria, Belgium, Czechoslovakia, Denmark, Finland, France, Hungary, Italy, Japan, Norway, Poland, Rumania, Russia, Serbia, Sweden, and the United States, will spend next week in London. The visit has been arranged by the Health Organization of the League of Nations, with the financial assistance of the Rockefeller Foundation, and the plans are being carried out by a committee of the Society of Medical Officers of Health, of which Mr. G. S. Elliston is secretary. The headquarters of the party will be at the offices of the society, 1, Upper Montague Street, Russell Square, W.C.1. On Monday the members of the party will be received by the Minister of Health and Sir George Newman, and a reception will be given in the evening by the Royal Sanitary Institute. On Tuesday morning they will visit the Ministry of Health and the R.A.M.C. College in the afternoon. On the next day they will visit Somerset House, will attend a reception by the League of Nations Union in the afternoon, and the Pasteur celebration at the Royal Society of Medicine in the evening. Thursday will be given to the Metropolitan Asylums Board, and Friday morning to the Metropolitan Water Board; in the afternoon the Lord Mayor will give a reception at the Mansion House. The morning of Saturday, March 3rd, will be devoted to the study of various housing schemes of the London County Council, and in the afternoon the party will leave to visit various provincial centres in groups of four or five. This is the second tour of the kind, Belgium and Italy having been visited on the first occasion.

#### THE CENSUS OF LONDON.

The Registrar-General is publishing the results of the census taken on June 19th, 1921, in county parts. The London part is being issued in three instalments, of which the first has been published this week. It comprises tables

relating to occupations, birthplaces and nationalities, and dependency and orphanhood; it in fact consists almost entirely of tables, which may account for the high price at which it is issued by the Stationery Office (8s.). The third instalment is to contain the explanatory text. Little of medical interest is to be extracted from the second. It appears that men are starting work at a later age and keeping on longer than was the case in 1911. Under the age of 14 employment has practically ceased. For women the principal occupations, in order of numerical importance, are "personal (mainly domestic) service," 357 per 1,000 total employed; "making of clothing," 145; "clerical," 125; "commerce and finance," 80. The institutional tables show a decline in the inmates of "Poor Law institutions" from 117 per 10,000 population in April, 1911, to 70 in June, 1921, and of 13.6 to 8.3 in the inmates of prisons and reformatories. There has been a considerable decrease in the alien population—from 338 to 266 per 10,000 inhabitants. Among the aliens, Russians, with 29,768, are most numerous, closely followed by Poles, with 26,923; French are a bad third, with 11,104, and Germans only 5,743. Stepney has by far the largest proportion of aliens, some 15 per cent. of the total population. The tables of dependency are given for the first time; their interpretation is difficult, and a fuller examination is deferred until complete results are available for the whole country, when the quality of the material can be more definitely established, and taken into account in the preparation of the subject volume, which is eventually to be issued. The tables will then be given showing for the whole country the number of married women, married men, widowers, widows, and husbands and wives jointly, with the number of children under 16 years of age, and particulars of the numbers and ages of the children in such families.

#### THE LATE DR. ELSWORTH OF SWANSEA.

The colleagues in and around Swansea of the late Dr. R. C. Elsworth, consulting surgeon to the Swansea General Hospital, have arranged to erect a memorial tablet to him within the hospital. It is thought that many of his friends would wish to be associated in this tribute to his memory, and subscriptions, limited to one guinea, may be sent to Dr. Edgar Reid, 164, St. Helens Road, Swansea, or Dr. A. Clarke Begg, 74, Walter Road, Swansea. The fund will be closed on March 15th.

## Scotland.

#### WORK OF THE CARNEGIE TRUST.

THE annual meeting of the Carnegie Trust held last week considered the twenty-first report, and as the scheme has now attained its majority a useful retrospect can be made of what it has achieved. Under the last quinquennial distribution of surplus funds, commencing in October, 1920, the sum of £224,300 was allocated among the universities and extramural colleges. Of this, £25,200 was applied towards providing books for libraries, £156,030 towards the cost of new buildings and permanent equipment, and £43,020 for endowment of lectureships and other general purposes. The St. Andrews Institute for Clinical Research is in receipt of a special grant of £1,000 for five years, and continues to give satisfactory reports of its activities. The wisdom of the scheme for giving assistance to students in the payment of class fees has been from the beginning questioned by many people. The amount so expended and the number of beneficiaries both show a progressive diminution. In the year 1920-21 the sum expended in this way was £65,284 19s. for 4,860 students; in 1921-22 the sum was £61,216 13s. on behalf of 4,779 persons; these are decreases of £4,068 6s. and 81 respectively. This particular part of the fund showed a deficit, however, amounting to over £1,000 for the year, which has been met from a special reserve fund established out of the sums voluntarily returned in this way are said to be of "not inconsiderable" amount it is generally believed that the attitude of those alumni who have benefited in the past twenty years has been disappointing, especially when the somewhat straitened present circumstances of the universities is considered. It is an interesting fact that the number of former women students who have repaid fees is considerably larger than the number of men. With regard to the second branch of this endowment—the encouragement of research by fellowships and scholarships—

the annual value of the latter has been reduced for the future to £175. The research fellows will continue to receive £250; in future they will be nominated by a professor or other head of a university department. It has been thought desirable that fellows, while devoting their whole-time service as before to the subject of their research, should spend part of this time on teaching it also. This plan should materially ease the financial difficulties of the universities in the payment of their junior staff.

#### MINE RESCUE INSTRUCTION.

A chair in mining has recently been endowed in the University of Edinburgh. The governors of the Heriot-Watt College in 1907 appointed a lecturer to give a course in this subject; it proved eminently successful, and the University later promoted an ordinance for granting a degree in mining, co-operating with the Heriot Trust so as to combine the teaching facilities of the University with those of the Heriot-Watt College. This department of mining has been very specially associated, through the researches of Professor Briggs, with the problem of increasing the safety of the miner in his occupation. For the immediate purpose of training rescue brigades attached to the collieries of the neighbouring coalfields, there has been constructed as the first instalment of a mining laboratory an underground shaft and galleries representing the actual conditions found in a coal mine after an explosion. This is situated in the Grassmarket site purchased by the governors of the Heriot-Watt College for the future laboratory, which it is hoped some wealthy benefactor may present to the University.

#### AN OLD-FASHIONED SURGEON.

The *Glasgow Medical Journal* of last month contains a lecture by Dr. J. C. McVail on the life and work of Dr. Borland, first surgeon to the Kilmarnock Infirmary. Borland was a born surgeon who practised in his own fashion, a kind of asepticism before the word aseptic had been invented. The Kilmarnock Infirmary was opened in 1868, when Listerism was in its Glasgow days, when the carbolic spray was used. Borland was too old-fashioned to have any belief in the spray and, for that matter, in the existence of harmful atmospheric germs, but he was a model of surgical cleanliness, a cool and skilful operator, and very wise in the matter of surgical treatment and dressings. His principle was dry dressing. He used silk ligatures not only for tying vessels but for drainage, bringing them out at the lower angle of every amputation wound. He avoided sponges, substituting for them old linen rags free from fibre. In compound fractures, after cutting away destroyed or dirty tissue, he applied dry lint into which blood soaked straight from the vessels, and so made a perfectly aseptic covering. By such means he achieved remarkable success. In major amputations his case mortality was less than half that obtained in the very best of the great hospitals in pre-Listerian days, and was quite as low as Lister's own under the antiseptic system of the early years. In secondary major amputations he had only two deaths in 63 cases; of 29 compound fractures all ended in recovery; in the later part of the period dealt with he had a series of 36 primary and secondary major amputations without a fatality. But the story is not confined to his work at the hospital. He was a notable man in his community, and played a man's part in the cholera epidemics of 1832 and 1849. That his life work was appreciated in his own town is manifest from the public acknowledgement his services received in connexion with epidemics, and at a great public gathering on the occasion of his professional jubilee. It is good to have the record of the doings of such a man, working away quietly in his local sphere, unconnected with teaching hospitals or medical schools, and continuing from beginning to end to do the work for the work's sake.

Kilmarnock Infirmary has indeed good reason to cherish the name and reputation of its first medical officer. He gave the institution a splendid start in its career of usefulness, and we have no doubt that the subsequent expansions of its activities, and its strong financial position at a time when many voluntary hospitals are in sore straits, is in some degree due to the impetus which it received from the great work performed by Dr. Borland.

#### GLASGOW ROYAL INFIRMARY.

The report for 1922 of the Glasgow Royal Infirmary states that the total amount received from all sources compared favourably with the previous year, while a welcome decrease in expenditure left the managers with a portion of the extra-

ordinary revenue available for the completion of the reconstruction scheme, and specially of the gatehouse block. The ordinary revenue was £80,964, which was only £928 less than in the previous year. The ordinary expenditure was £104,813, showing a decrease of £13,436, mainly in fuel, lighting, provisions, etc. The ordinary revenue failed to meet the ordinary expenditure by £23,848, but this was an improvement on the previous year. Annual subscriptions amounted to £20,517, and contributions by employees in public works, etc., to £29,030. Legacies amounting to £19,387 and donations amounting to £20,350 were received during the year, and special donations amounting to £11,845 were received from various endowments, including six more beds; eighty-three beds and six cots are now endowed. During the year 11,362 patients were under treatment in the wards, being 541 more than during the previous year; the daily average of in-patients was 657.9. The rate of mortality was less, and the average time of residence of patients under treatment was reduced from 23 to 21.1 days. In the outpatient department 44,689 patients attended, an increase of 2,800 from 1921, and the total number of attendances was 188,532; in the ophthalmic institution 778 in patients and 12,524 out-patients were treated; while 954 persons were admitted during the year to the convalescent home.

#### GLASGOW ROYAL ASYLUM.

The annual meeting of the Glasgow Royal Asylum was held on February 15th, when Dr. D. K. Henderson, physician-superintendent, presented his annual report. The total number of patients under treatment during the year was 657, and the average number resident 515. The number of admissions was 145, and 153 patients were discharged, of whom 50 had recovered, 28 were greatly improved, and 29 were not improved; there were 46 deaths. The great bulk of the cases were of a functional nature, and in the majority of the others the conditions were attributed either to alcohol or syphilis, or to the changes incidental to old age. The fact that 41 patients applied voluntarily for admission afforded gratifying evidence that the stigma attached to mental disorder was passing away, and that it was being looked upon as an illness which could be treated and benefited. It had been the custom for many years to keep a separate record of those cases which were directly due to intemperance, and not infrequently the number had been over 20 per cent.; during more recent years this percentage had shown a definite decrease, and last year the percentage of cases due to alcohol had amounted to only a fraction over 6 per cent. Dr. Henderson said that the enlightened policy of the directors in providing a nursing home for the treatment of incipient mental disorders, outside the institution, had been greatly appreciated.

#### CRIME IN SCOTLAND.

Dr. Robert A. Fleming, physician to the Royal Infirmary, Edinburgh, and senior lecturer on clinical medicine in the University, has been appointed by the Secretary for Scotland to be Medical Adviser to the Prison Commissioners for Scotland, in succession to the late Dr. Harry Rainy.

The Commissioners in their report for 1921, recently issued, state that the total number of persons convicted during the year by the criminal courts was 115,571, a decrease of 27,504, or 19.2 per cent., on the number for the previous year. This is due mainly to a diminution under the headings of such minor offences as breach of the peace and drunkenness; and there was a marked increase in the number of persons against whom proceedings were taken for serious crime, the total being 25,764. Of these, 47 persons were charged with murder and 14 with attempted murder, but there was no conviction for murder during the year. The rapid increase in the numbers sentenced to penal servitude since 1918 is a disquieting feature and is shown by the following figures: in 1918, 42; 1919, 58; 1920, 76; 1921, 117. The number of persons tried in the juvenile courts during 1921 was 7,922, a very slight increase on the number, 7,839, for 1920. There has been a steady reduction in applications for licences for inns, hotels, public houses, etc., these having numbered in 1919, 9,497; in 1920, 9,448; and in 1921, 9,251.

#### CENTRAL MIDWIVES BOARD.

At the recent examination of the Central Midwives Board for Scotland, held simultaneously in Edinburgh, Glasgow, Dundee, and Aberdeen, 123 candidates appeared; of these 113 were successful and 10 were rejected. Of the successful candidates

28 were trained at the Royal Maternity Hospital, Edinburgh, 41 at the Royal Maternity Hospital, Glasgow, 4 at the Maternity Hospital, Aberdeen, 11 at the Maternity Hospital, Dundee, 4 at the Queen Victoria Jubilee Institute, Edinburgh, 7 at the Cottage Nurses' Training Home, Govan, Glasgow, and the remainder at various recognized institutions.

#### CENSUS OF DUMBARTONSHIRE, 1921.

This thickly populated county extends along the northern shore of the tidal Clyde from the western boundary of Glasgow to Loch Long, and northwards to Loch Lomond; there is also a detached part, between Lanarkshire and Stirlingshire, composed of two parishes. Apart from the region of the lochs, the county is within the busiest part of the industrial area of Scotland, and the population has increased from 20,710 in 1801 to 150,861 in 1921. The growth of Clydebank has been phenomenal; in 1881 it was a village with a population of 1,643; it is now a burgh with 46,505 inhabitants. Shipbuilding and the manufacture of sewing machines are its chief industries. The burgh of Dumbarton, at the mouth of the river Leven, is also an important shipbuilding centre. Along the banks of the Leven, which carries the waters of Loch Lomond to the Clyde, the industries are textile—turkey-red dyeing and calico printing. Of the total population of the county engaged in occupations, 29.9 per cent. are workers in metals and only 4 per cent. are in agriculture. The urban population is 64.1 of the total, but a large part of the non-urban area is urban in character, and has been provided under county council government with urban facilities, such as water, drainage, scavenging, and lighting. In one-roomed homes there live 7.7 per cent. of the population, in two-roomed 47.4, and in three-roomed 20.3. The excess of females over males is only 3.5 per cent.; in 1911 it was only 0.5 per cent. Gaelic speakers are only 1.3 per cent. of the population, and all of them are bilingual.

## Ireland.

#### THE ASSOCIATED DUBLIN HOSPITALS AND THE TREATMENT OF INSURED PERSONS.

It is stated that agreements are being entered into between the Board of Representatives of the Dublin hospitals and branches of the workers' unions by which the latter, for small weekly contributions, will receive for themselves and their dependants not only intern treatment in the wards, but also treatment in the external departments of the hospitals. Arrangements are, moreover, being made with the Irish Insurance Commission whereby insured persons may receive hospital treatment as a benefit. For the most part insured persons receive their medical treatment as "poor persons" under the Medical Charities Acts owing to medical benefits not being included in the Insurance Act in its application to Ireland. It is believed that the arrangements made between the governors of the hospitals and the workers' unions will not be acceptable to the honorary medical staffs of the hospitals, as to do so would at once bring them into conflict with the general medical practitioners and their interests.

#### DUBLIN CORPORATION AND TREATMENT OF TUBERCULOSIS.

The Dublin Corporation is to consider a report from its Tuberculosis Subcommittee with regard to the question of payment for the treatment of tuberculous children in Cappagh Convalescent Home and Tuberculosis Hospital. The report states that in September, 1920, payments by the Tuberculosis Committee to the hospital on account of child patients were suspended. Such patients, however, continued to receive treatment, and in November, 1922, the Corporation resolved that the question of resuming the payments should be favourably considered. Prior to September, 1920, payments had been made for an average of 15 tuberculous children. The discontinuance of the payments was caused by the withholding by the Government of the grant-in-aid. It was decided to transfer the children to Crooksling Sanatorium, but the children's parents declined to allow them to be removed; the number now at the sanatorium does not exceed 15 or 20. The Committee realizes that the conditions under which children are at present treated in Crooksling Sanatorium leave much to be desired. The Acting Resident Medical Surgeon has reported that treatment of children cannot be properly undertaken unless absolute segregation is ensured.

The Committee concurs with his view that the erection of a self-contained pavilion for children, with nursing, dining, school, and recreation accommodation, with a separate nursing and domestic staff, is necessary. The city architect, after paying a visit to Peamount Sanatorium, where there is a self-contained children's pavilion, has reported that the cost of the proposed building would be approximately £8,000 to accommodate about 50 children. The extra staff would involve an expenditure of about £1,325 per annum. The number of city children at present under treatment in Cappagh for tuberculosis is between 25 and 30, and the rate of charge would be £1 1s. a week. Were the Corporation to undertake liability for these patients the cost would be about £1,400 to £1,600 a year. If the number of children at present being treated at Crooksling Sanatorium were to be transferred to Cappagh the extra cost would be about £800 to £1,100 a year.

#### MULLINGAR MEDICAL OFFICERS.

At a recent meeting of the Mullingar District Council, which is temporarily administering the Medical Charities Acts since the abolition of the local Board of Guardians, the question of increasing the salaries of the dispensary doctors of the union was considered and the following scale was unanimously adopted: An initial salary of £250 per annum, reaching a maximal salary of £350 by annual increments of £5. The scale is made retrospective, and £50 of the scale is to go towards travelling expenses. The latter condition means that a recently appointed medical officer will at once come into a salary of £300 and those with ten years' service will immediately attain the maximum of £350 per annum. Dr. Hennessy, Irish Medical Secretary, attended the meeting of the council and stated the case of the medical officers.

## India.

#### PAYMENTS BY HOSPITAL PATIENTS.

Owing to the serious rise in the cost of maintenance of all Government hospitals in India, especially those in Calcutta, it has been necessary to seek for new sources of income in order that no fresh burdens might be placed on provincial revenues at the present time. As the capacity of the hospitals in Calcutta was already taxed to the full it was impossible to restore equilibrium by closing down a few wards, and it has been necessary to institute a levy of moderate charges on all patients, whether indoor or outdoor, who could afford to pay them. There are at present 1,600 free beds in the Calcutta hospitals, and of these it has been decided to reserve 850 beds for free occupation by the poor and indigent, allocated as follows: Medical College Hospital, 40; Shambhunath Pandit Hospital, 60. The largest number of free beds has thus been allocated to those hospitals which are used mainly by the poorer classes. At the Medical College, Campbell, and Shambhunath Pandit Hospitals 8 annas a head a day is to be charged; at the Medical College Hospital an extra charge of 1 rupee a day will be made for cubicles, and of 2 to 8 rupees for private rooms; at the Presidency General Hospital, where the charges in the paying wards were recently increased, a daily flat rate of 1 rupee a head will be charged both for indoor and outdoor patients. Hospital superintendents are, however, given discretion to remit the charges of any patients who in their opinion are incapable of paying the fees.

#### RANCHI EUROPEAN MENTAL HOSPITAL.

Details have been published regarding the ultimate condition of patients discharged during the past three years from the Ranchi European Mental Hospital, the principal mental hospital for Europeans in India. There is as yet no social service organization in India through whose agency the hospital can keep in touch with its ex-patients, but information was obtained, either from the patients themselves or from their friends or relatives, which throws a very favourable light upon their treatment in hospital. Of the total number of patients treated at the Ranchi Hospital since November 1st, 1919, 78 were discharged down to November 30th, 1922; 5 had been lost sight of; of the 73 others 29 are now living with friends or relatives, but are still unable to support themselves, 14 are supporting themselves in some career or other, and 25 are known to be pursuing their

original vocation. Of the 73, 6 have been out of hospital for upwards of thirty months, 14 for between twenty-four and thirty months, 14 between eighteen and twenty-four months, 17 between twelve and eighteen months, and 22 under twelve months.

#### CHILD WIVES IN CALCUTTA.

According to the last census of Bengal, which is now nearing completion, there were 18,256 child wives in Calcutta; 14,749 were between 10 and 15 years of age; 2,696 children under 15 years were widowed. Out of a total Christian population in Calcutta of 39,154 there were 20,962 unmarried and 15,567 married; the unmarried females numbered 8,850, and the males 12,112.

#### CHILD WELFARE IN INDIA.

Lady Lytton, when presiding at a meeting in Calcutta under the auspices of the Bengal branch of the Indian Red Cross Society, said that when touring last summer in Eastern Bengal she had been much struck by the need for welfare centres and also by the eagerness of the people to have them established in their villages. She intended to do all in her power to encourage that work in order that the many divisions of Bengal might in time benefit by such centres as that in Calcutta; though welfare work was still in its infancy there, Calcutta had every reason to be proud of the St. John Ambulance and Red Cross voluntary workers, without whose help the welfare movement could not have been begun.

## Correspondence.

#### SMALL-POX AND VACCINATION.

SIR,—I have followed with much interest the correspondence on "Small-pox and Vaccination" in the *JOURNAL* during the latter part of 1922. In your issue of December 23rd (p. 1243) Dr. Millard says "that in 1915 the State of New York, acting on the advice of their health officer, Dr. Herman Biggs, virtually abolished compulsory vaccination by repealing the regulation under which all children had to produce evidence of vaccination before being admitted to school." He states further that this advice was given "because he [Dr. Biggs] had come to believe that the disadvantages, in the way of injury to health caused by child vaccination, more than outweighed the advantages to be gained by immunization against a rare disease like small-pox."

Such a statement misrepresents the attitude of Dr. Biggs, and is apt to do great harm to a procedure which has proven itself of such enormous value. I have just received from Dr. Biggs the following statement:

"The quotation as regards my attitude towards vaccination is, of course, incorrect.

"In 1915 we had a very unfortunate experience. In the course of a campaign for bringing about more general vaccination, as a result of which a very large number of vaccinations were made in the State, we had a number of cases of tetanus, with ten or eleven deaths—I think it was eleven deaths. Naturally there was an enormous amount of publicity and a violent reaction to compulsory vaccination. Legislation was introduced which would have repealed all of the provisions of the vaccination law, and the question came up as to what was the wise thing to do under the existing conditions. I felt that to insist on compulsory vaccination under the conditions was not justifiable and was unwise, and that it would injure the whole public health programme; and, furthermore, that it would interfere with the accomplishment of our purpose rather than forward it. We therefore consented to the amendment of the law, the provisions of which, as they now stand, are described in the enclosed."

It is evident that unfortunate accidents due to impure vaccine matter brought about his consent to an amendment, feeling that it would be better to do this than to lose out on the whole vaccination programme. He did not at that time believe, nor does he now believe, that vaccination in childhood produces any injury to the health of the child, and to quote him as Dr. Millard did is entirely misleading.

I may add, further, that at the present time all vaccine virus produced in the United States is under the supervision of our Public Health Service, and such deplorable accidents as have occurred in the past are not heard of at the present time.—I am, etc.,

MAYZEC P. RAVENEL, M.D.

University of Missouri, Columbia, Jan. 31st.

## PHYSIOLOGICAL CONSEQUENCES OF GASTRO-ENTEROSTOMY.

SIR,—In criticizing simple gastro-enterostomy as an operation for the cure of chronic gastric ulcer, and after discrediting the "physiological" action which has been claimed as a beneficial factor in this method of treatment, Sir Berkeley Moynihan (*BRITISH MEDICAL JOURNAL*, February 10th, p. 221) sums up by saying, "gastro-enterostomy acts mechanically, and in no other way." Is this statement as it stands entirely acceptable? I inquire; I do not presume to criticize. Is it safe, in the light of present knowledge, to assume that gastro-enterostomy is devoid of physiological consequences?

One of the essential features of a successful gastro-enterostomy is that the duodenum is more or less short-circuited. In order to appreciate the physiological consequences of this condition it is convenient to consider the effects of a complete short circuit. This note is prompted by recent experimental experiences (unpublished), in which I found that chronic peptic jejunal ulcer was the constant sequel of gastro-enterostomy with pyloric exclusion, in dogs. If careful dieting and alkali treatment was not observed, extensive acute jejunal ulceration was liable to follow the operation. The stools showed evidence of both pancreatic and biliary deficiency; at a second laparotomy the bile ducts were observed to be dilated in two instances. I interpret these observations as follows:

(a) The internal secretion of the duodenum, secretin, is deficient, because acid does not pass through the duodenum. This substance being the main source of stimulus to pancreatic and biliary secretion, an insufficiency of pancreatic juice and bile is caused.

(b) The sphincter of Oddi remains tonically contracted, as the local action of acid chyme, which causes its relaxation, is absent. A mechanical obstruction to the flow of bile results.

(c) The external secretion of the duodenum, which contributes a considerable proportion of the succus entericus, is decreased by the same cause.

(d) It may also be noted that Brunner's glands are probably deranged, though I cannot at present tell what significance this may have.

The jejunal ulceration is, no doubt, largely dependent on the combined deficiency of alkaline secretions. Clinical evidence as to the physiological consequences of duodenal short circuit points in the same direction.<sup>1</sup> While gastro-enterostomy for gastric ulcer does not imply complete short circuit, it is not probable that according as the chyme traversing the duodenum is decreased so will its functional activity be impaired and the consequences outlined above ensue in greater or lesser degree?

In view of the above considerations it is interesting to note the extraordinary success of the partial gastrectomy practised by Sir Berkeley, for in his operation the duodenum is completely short-circuited. Assuming that the pancreatic, biliary, and duodenal secretions are decreased, how is the freedom from post-operative complications, which his patients enjoy, to be explained? Is the experimental inference valueless? The explanation which suggests itself is that after partial gastrectomy for ulcer the acid secretion of the stomach is permanently diminished (a) by removal of a considerable portion of the acid-secreting tissue, (b) by removal of the pyloric antrum, the reputed source of gastrin (the hormonal excitator of acid secretion), (c) by permanent impairment of the gastric mucosa by long-standing catarrh antecedent to operation, so that it never regains its full secretory power. One is tempted, on theoretical grounds, to wonder if idealism is carried further by conservation of the normal physiological activity of the duodenum, as in the Billroth I, Kocher, and Schoemaker methods of gastrectomy.—I am, etc.,

Colinton, Edinburgh, Feb. 12th.

NORMAN M. DOTT.

#### A PLANORBIS AS THE INTERMEDIATE HOST OF SCHISTOSOMA HAEMATOBIIUM.

SIR.—The authors of the report of the mission of the Institut Camara Pestana for the study of bilharziasis in Portugal have kindly sent me a copy, and the results obtained are so greatly at variance with all former experience that I venture to draw attention to them. The chief points are:

1. Endemic vesical schistosomiasis occurs at Tavira in Portugal, the infective site being a small collection of water, built round to form a place for the washing of clothes.

2. Infection of the water is due to the washerwomen urinating there, examination of the urine of these women showing the

<sup>1</sup> "Post-operative Jejunal Ulcer," *Med. Science*, 1923, vii, 225-253.

presence of ova of *S. haematobium* (of 64 women examined, 46 were infected).

3. The only molluscs found in the pool were *Physa acuta* and *Planorbis metidjensis*.

4. In no case were cercariae found in *Physa acuta*, but they were found in *Planorbis metidjensis* (in 17 out of 253 examined).

5. The cercariae corresponded in every particular with the published description of the cercariae of *S. haematobium*.

6. In laboratory experiments miracidia were not attracted to and did not penetrate *Physa*; but were strongly attracted to and were seen to penetrate *Planorbis*, although further development up to the stage of cercariae was not observed.

7. Laboratory experiments resulted in the infection of a proportion of mice after immersion in water containing cercariae obtained from *Planorbis*; 7 mice were immersed, and of these, 4 showed later, on autopsy, the presence of adult schistosomes, already paired, and presenting the morphological characters of *S. haematobium*, in the portal vein and its ramifications; one, killed earlier for examination, showed typical eggs in the blood of the portal vein, although no worm was seen.

The authors conclude that these experiments on mice afford absolute confirmation of the statement that *Planorbis metidjensis* is the intermediate host of *S. haematobium* at Tavra.

Hitherto the genus *Planorbis* has been believed to furnish a species which is exclusively the host of *S. mansoni*, and the report quoted is the first where record is made of a species of this genus acting as the intermediate host of *S. haematobium*; it is therefore highly desirable that confirmation of these results should be forthcoming from an independent source.

If it is accepted that this species of a genus till now regarded as unconnected with the life history of *S. haematobium* is capable of acting as the intermediate host, the question of the possibility of the spread of urinary schistosomiasis is greatly enlarged; and again, there arises the possibility of bilharziasis making its appearance in Australia through the infection of a suitable gastropod host by the ova passed in the urine of Australian soldiers, infected in Egypt during the great war and not yet cured.—I am, etc.,

GEORGE A. WILLIAMSON.

Aberdeen, Feb. 13th.

### THE SURGERY OF THE PROSTATE.

SIR.—It is unusual for surgical operations involving the bladder to be associated with charm; still, Sir John Thomson-Walker's pleasantry in his reply (February 17th, p. 304) to my criticisms of "open" prostatectomy may afford amusement. I was more interested in his observations on Dr. E. S. Judd's paper (*Mayo Clinic Reports*, 1916), to which I referred in my letter of February 10th. He has looked up my reference, and finds therein "illustrations, but no descriptions, of an open operation where the prostate is being partly dissected and partly enucleated by the finger in the Trendelenburg position." I can find no illustration in that paper depicting a dissection of the prostate. The customary legends attached to each illustration—there are several of them—seem to have escaped Sir John's notice. They supply an ample description of the operation.

He condemns enucleation and dissection of the prostate in the Trendelenburg position as "cumbersome and unsatisfactory," and adds that "the operation illustrated in Dr. Judd's article, and which I saw him perform, is not the operation I described." Frankly, I am at a loss to know in what essential points of technique they differ. In the Trendelenburg position both use retractors within the bladder—though not of identical pattern; insert a haemostatic suture in the prostatic capsule, and close the bladder incision up to a tube by continuous suture. Essentially, as far as one can gather from their respective descriptions, the operations are identical.

I have previously submitted, and I trust with due deference to authority, that open prostatectomy is a difficult and unnecessary operation—unnecessary, in that it has been developed to meet those complications of haemorrhage and sepsis which, to a dangerous degree, seldom occur in the modern practice of suprapubic prostatectomy by the method of Freyer. Nor is it in any spirit of carping criticism that I have made some observations on the address of a recognized leader in genito-urinary surgery. My only desire is to remove the prostate by the method which "gives the best result for the patient." In the past I have enucleated the gland by a method commonly practised in this country; none the less, I am very interested in any method which gives "better results." If some of the "many general surgeons" known to practise the open operation described by Sir John Thomson-Walker would publish a series of cases they would go far to establish its place in the surgery of the prostate. In the

meantime, like others, I shall have to be satisfied with the proved efficiency of "blind" prostatectomy.—I am, etc.,

Dukinfield, Cheshire, Feb. 18th.

GERALD RALPHS.

### TRAUMA AND APPENDICITIS.

SIR.—Under the above heading in your issue of January 6th Dr. Taylor records two cases of appendicitis associated with, probably caused by, trauma. In a paper entitled "An analysis of 4,656 *post-mortem* examinations held at the Government Mortuary, Johannesburg" (a reprint from which I send you), I draw attention to the case of a native who, on March 2nd, 1918, was struck in the abdomen with a stone by another native. He was admitted to the General Hospital, Johannesburg, on March 3rd, and died on March 5th without being operated on. I performed a *post-mortem* examination and found the cause of death to be peritonitis due to a ruptured appendix. When I read this paper before the Witwatersrand Branch of the British Medical Association I asked the question, "Was the ruptured appendix caused by the assault?" but got no reply.—I am, etc.,

JOSEPH J. LEVIN,

Extra Honorary Surgeon, Johannesburg Hospital.

Johannesburg, Jan. 31st.

### A PLEA FOR MANUAL TRAINING.

SIR.—The Consultative Committee's report on sex and school courses, of which an account is published in the *BRITISH MEDICAL JOURNAL* of February 17th (p. 292), affords very instructive reading. In this letter I only propose to refer to one of the subjects mentioned in that report—that is, music—as it appears to me to be dealt with in rather a perfunctory and inadequate manner.

Music is more and more coming to the front, and rightly so, in the education of boys and girls, not only for its elevating and refining influence on character and behaviour generally, but also, and quite apart from the beauty of music as a fine art, for its educative power and as being one of the best possible methods for the teaching of manual dexterity. The fact that, in the new regulations of the Oxford and Cambridge Schools Examination Board, music has just been placed on a parity with the other subjects for the School Certificate and the Higher Certificate examinations is a sure proof that the authorities of our two ancient universities have satisfied themselves of its great value as an educational force.

The tendency of the present day is towards a dead and dry materialism, which music helps largely to counteract and to replace by a more spiritual and uplifting atmosphere, which cannot fail to influence for good the growing and expanding mind of youth—whether boy or girl.

For the development of manual dexterity—as, for instance, in the case of an ophthalmic surgeon, or, indeed, for any operating surgeon—I can imagine no better training than learning to play a musical instrument, such as the piano or the organ, and preferably, perhaps, the former. Such a training gives precision and ambidexterity, independence and flexibility of fingers and wrist, and delicacy and lightness of touch and manipulation, in a way that it would be difficult to overestimate. I do not mean to say, of course, that the training of the hands can only be accomplished by first learning to play a musical instrument, as there are many other methods for the unmusical by which it can be attained; but I think it is a decided defect that such training has no place in the curriculum of the medical schools of this country, except such as can be obtained in the dissecting room, which is, no doubt, good, so far as it goes. Speaking for myself I can only say that I have found pianoforte playing of the greatest possible help as a manual training in the practice of operative surgery and in the carrying out of all the various surgical manipulations that one has constantly to deal with in one's daily work.

Any amount of trouble is expended in teaching students how to carry out the details of antiseptic and aseptic surgery; might not a little of that time and energy be quite as profitably employed in teaching them how to use their hands with gentleness, lightness, and precision?

I well remember on one occasion, many years ago, going round the wards of a hospital with a very eminent surgeon in this country, when he asked a student to percuss the chest of one of the patients. After the student had completed his examination the surgeon, addressing him, said: "I think, Mr. —, we may safely conclude that you do not play the pianoforte!" It is not difficult to imagine from that remark

what the effects of the student's clumsy and rough attempts at percussion were on the poor emaciated patient.

All surgical operations, and certainly the more difficult and delicate ones, necessitate, of course, a more or less high degree of manual dexterity, but even the most difficult and complicated operative measures in surgery do not require anything like the manual skill that is requisite for a musician who has to play a difficult piece of music—say a Bach fugue—correctly and intelligently. It is a fortunate thing that such is the case, otherwise it would be a bad look-out for a large number of patients who, sooner or later, have to come under the surgeon's knife.

In general surgery there is usually a certain amount of what one may term margin for error, very little margin indeed in ophthalmic surgery, and practically none in music.

Referring once more to the Consultative Committee's Report, I would say that in music, as far as my observations go, the girls are, perhaps, equal to the boys in technique, but are very far below them in creative power, such as in extemporization or in composition.—I am, etc.,

Gloucester, Feb. 17th.

E. DYKES BOWER.

\* \* By the same post we received a note from Dr. Charles J. Hill Aitken (Kilbarst, near Rotherham) entitled, "Wool rug making an aid to surgery." He writes: A well known surgeon lecturing on abdominal surgery told his students that if they wished to become experts at bowel operations they must start by learning to darn their socks—a statement that probably amused many of his hearers. For the last few months I have been making a wool rug, and having occasion to do a small operation the other day—the first for a long time—I was delighted to find how steady my hands and deft my fingers were. To the general practitioner who rather dreads his occasional operation because of possible clumsy fingers I can recommend wool rug making.

#### THE MEDICAL PROFESSION IN WAR.

Sir,—During the recent discussion at the Royal Society of Medicine on February 12th (SUPPLEMENT, February 17th, p. 52) regarding co-operation between the medical profession and the naval and military and air branches, we listened to many useful ideas, especially those in the fine paper of Surgeon Captain MacKicown, R.N., but no definite resolution was put forward. I should like to emphasize two suggestions I made.

The bar to complete concert in war is want of understanding, want of clear grasp of the different points of view of civilians and service members. Taken broadly the civilian idea is to carry out professional duties only, with little or no sympathy for the functions of the service officer, yet the duties of the latter are so complex that pure professional work forms only a part of the wide sphere of duty for which he is strictly responsible, initially to the D.G. of his service, then to the Admiralty or War Office or Air Ministry, eventually to Parliament. To obtain efficient co-ordinated work it is absolutely essential that there should be mutual understanding, and this is to be obtained only by widespread friendly conversations, not in London alone, but everywhere throughout the Empire. How is this to be brought about?

In my opinion, the best plan is to utilize the existent machinery of the British Medical Association and of the Territorial forces. The Directors-General of the Naval and Military Medical Services should issue distinct orders to all senior officers to call upon the local Branch of the British Medical Association and to attend their meetings when possible. This act of courtesy is in accordance with the custom of the medical profession when a member is about to take up a practice in a town. It at once establishes an *entente cordiale* and leads to those social amenities, conversations, and friendships which foster mutual understanding and to a true conception of ideas and of the difficulties that each has met with or anticipates.

The Branches of the British Medical Association should on their side impress upon their younger members the duty of joining one or other of the Territorial units, and while serving therein of studying, not their professional work in particular, but the complexities in recruiting and invaliding and pensions, in case recording, dieting and clothing, in sanitation in barracks and camps, in indenting for drugs and appliances, and in economizing expenditure, in office work and financial details, in the management of the N.C.O.s and men of the R.A.M.C., and in many other points.

But, says the purely professional man, I am concerned with none of these things. Quite so. He is then apt to become the fifth wheel of a coach, ornamental and only occasionally useful. His want of understanding may indeed transform him into an actual drag. Suppose, for instance, a naval or army medical officer was attached for duty to a great civilian hospital and declined to accept or to conform to the ideas of management therein, of a system which is the outcome of long experience?

One speaker said the Aug'o-Saxons were a slow-thinking race. It is quite true. They could not realize the German menace, although Lord Roberts preached his warnings incessantly. They do not now realize that Germany, Russia, and Turkey may at any moment combine against us. They do not grasp the dangers of Bolshevism although the Duke of Northumberland, in his weekly paper *The Patriot*, sets these forth very clearly. Each citizen is concerned chiefly if not alone with his own petty interests.

War makes two demands upon each loyal and patriotic citizen: first, that he should carry out his own specialty so as to render the greatest service possible; secondly, that he should not impede the functions of others. Only by mutual understanding can these two demands be effectively combined. Schemes and systems, hard and cut and dry, are all very well, but they need the emollient influence of personal conversations, friendships, realization of each other's aims and of difficulties. Therefore in every city and every town, in every small station and in every far-away port, the method should be to bring the newcomer into touch with the older resident; and to make the resident part and parcel of the local naval or military organization.

There is much more to be said on various points, and much also upon the advantage of studying naval and military tactics and strategy in addition to medical organization, but your space is limited.—I am, etc.,

T. M. CORKER,

London, W., Feb. 15th.

Major-General A.M.S. (ret.).

#### HOSPITAL POLICY.

Sir,—In your issue of February 17th (p. 303) appears a proposal by Dr. L. S. Luckham, President of the Salisbury Infirmary League, that instead of the staff of a voluntary hospital being paid, or even receiving a nominal fee for work done for those patients who are not indigent, they should be content to enter into a pension fund scheme. He adds that this would probably meet with the contributors' approval. Probably it would; owing to its remoteness.

From repeated talks, circulars received, and schemes issued it would seem that the greatest confusion is gradually arising, and in the resultant chaos the prestige of medicine as a science will deteriorate. I would venture therefore to urge that the true position must be defined clearly, and in order to assist in this would submit the following statement for general approval:

1. Voluntary hospitals were built for the indigent poor—that is, for those unable in any way to contribute for their medical treatment.
2. The charitable found the money and doctors the services.
3. These hospitals are now required for the indigent poor only to the extent of 15 per cent.
4. The surplus accommodation (85 per cent.) is put at the disposal of those who indirectly or directly are able to pay in full for medical treatment.\*
5. For those under an agreed income limit who pay through a contributory scheme the premiums should be fixed at such a level as will allow of full payment being made from the fund to the hospital. These persons, whatever their individual financial position may be, are no longer objects of hospital charity. Any financial assistance given by the charitable public should be paid to the fund and not to the hospital direct. Those above the income limit could also pay into the scheme, but at such a premium as will make them eligible as private patients for beds either in the private wards of the hospital or at recognized nursing homes.
6. The Board of Management, therefore, should see that not one penny of the funds received from charitable sources is used for this 85 per cent. A separate account should be kept.
7. The tariff of payments fixed for this 85 per cent. should be such as to pay in full the whole cost to the hospital, including remuneration of the staff.
8. Owing to the economic conditions at present existing the staff should be willing temporarily, without prejudice and as a concession, to receive a nominal recognition of the services rendered, by means of a percentage payment.

\* These include those paid for by Ministries of Pensions, War, Admiralty, Education, and Health, municipal authorities, employers of labour, approved societies, insurance companies, etc., or under a contributory scheme where there is a stated or implied return required from the hospital.

9. By this concession the Board of Management will be able to fix a lower tariff of fees than it otherwise could for the reception of this 85 per cent.

10. If the staff gives its services for nothing to this 85 per cent. they are thereby underselling their colleagues in their district, many of whom are equally competent to be on the staff as themselves.

11. The consequent loss of experience and income to these colleagues will result in (a) the deterioration of medical skill in the district through competent practitioners being unable to obtain a livelihood and having to leave; (b) loss of a chance of skilled attention for those of the public able to pay private fees; and eventually to (c) the provision of a second or third rate staff for the hospital itself. The whole status of medicine in England will go down.

If this general statement of the position is correct it becomes very difficult to see why the staff should be asked to be content with a suggested pension scheme instead of payment for work done. One has never heard this proposal made in relation to club or national insurance domiciliary practice as an alternative to the accepted mode of payment adopted so far. Why, then, should it prove acceptable for hospital practice?—I am, etc.,

Hove, Feb. 12th.

E. ROWLAND FOTHERGILL.

P.S.—The present sentiment displayed for those who are mentally unsound or who are on the border-line, admirable as it is in the abstract, will, if allowed to develop its schemes for free medical services for all, tend to the deterioration of this branch of medicine, as suggested above. The situation requires watching very closely. It is very doubtful whether those who are giving their medical services free to these patients realize what it may lead to.

#### INDIAN MEDICAL SERVICE.

SIR,—The terms of the advertisement in your issue of December 16th, 1922, of thirty vacancies in the Indian Medical Service are likely to mislead possible applicants; and in the opinion of many I.M.S. officers it is time that the India Office altered its description of the attractions of the service to bring it more in line with the facts.

However hopeless it may be to look for improvement in one's own position, one has a right to object to the unvarying repetition of these statements, which are likely to mislead others.

(a) "*He may apply after two years' Indian service for transfer to the civil side.*" etc.—This is true literally; but if it is meant to imply that the European officer has any chance whatever of transfer to the civil side soon after two years' Indian service, it is simply untrue. Even before the war the average period was about six years; while since the war officers of ten years' service and more have been refused civil employment on the ground of military necessities. I think I am right in saying that no European officers have been given civil surrogencies since the war, except those who had held these posts before 1914 and so had a claim to them. Not one of the thirty officers now called for will have any reasonable prospect of leaving military employment under the present system.

(b) "*Private Practice.*"—As this is practically non-existent, the advertisement should not hold it out as a bait to these military officers.

(c) "*Increased Cadre.*"—It should be widely known that since 1918 no study leave, as such, has been granted to military officers of the I.M.S. That is to say, an officer desirous of doing study has to convert his ordinary leave and furlough into study leave, and so, of course, by that amount forfeit the real leave which he requires after years in the tropics. In fact, as regards study leave, their position is exactly as it was before the loudly advertised new regulations were drawn up.—I am, etc.,

January 18th.

PROTEST.

SIR,—In your issue of December 30th, 1922, an advertisement re recruitment for the Indian Medical Service is published. I would be glad if you could spare space for a few remarks on the passage headed "careers." In the third line occur the words "military side, which has medical charge of the Indian army." This is not so. The R.A.M.C. hold at the least as many administrative appointments as the I.M.S.; the relative strength of the troops is about one Britisher to four Indians. I know of at least two Indian general hospitals commanded by R.A.M.C. officers. In line 7: "or a specialist post." The possession of specialist qualifications is of practically no assistance in obtaining such posts. Later: "He may

apply after two years' Indian service for transfer to the civil side." Quite, and possibly get on the civil side after twelve to fourteen years' service. Further on a reference is made to "professorships in the medical schools." Practically all such appointments are now in the hands of the Indian Ministers of Education for the various provinces; they are no longer reserved for the I.M.S.

Pay is absolutely comfortable for a bachelor and hopeless for a married man. The effect of the "increased cadre" appears to be the abolition of the usual two months' leave in the hot weather, for Europeans at any rate, and a great curtailment of home leave.

The best advertisement for any service is a contented body of officers in that service, a fact which the authorities do not appear to realize.—I am, etc.,

January 19th.

I. M. S.

#### "T.B."

SIR,—May I once again call attention to the misuse of the abbreviation "T.B." or "t.b.," and the serious errors to which it may give rise? The abbreviation is now commonly used to signify not only "tubercle bacilli"—which is its proper use—but also "tuberculosis" or "tuberculous," which is entirely improper and often misleading. The following instances of the abuse of this abbreviation are culled from various documents:

"The patient should be under the supervision of the Dispensary T.b."

"No T.b. bacilli in sputum."

"T.B. of lungs. . . . T.B. not found in sputum."

"T.B. not found."

The last instance, owing to the confusion occasioned by the varying significance of the abbreviation, leaves one in doubt as to whether the meaning is "No tuberculosis was found," or only "No tubercle bacilli found." Properly it should signify the latter, but from a study of the context it seems probable that the former was meant, and that in fact an examination of the sputum had not been made. The same uncertainty has arisen in several other cases, in like manner.

The Ministry of Pensions seems to set the fashion by appointing special medical officers with the title "D.C.M.S. (T.b.," and by officially addressing tuberculosis officers as "T.B. Officer." As might be expected, therefore, many instances of the abuse of the abbreviation "t.b." are to be found in Ministry of Pensions reports; but unhappily the Public Health Tuberculosis Service appears to have followed suit. The matter is surely one that calls for authoritative action.—I am, etc.,

E. WEATHERHEAD, M.B.Camb.

Alderley Edge, Cheshire, Feb. 8th.

#### STANDARDS OF VISION IN COUNCIL SCHOOLS.

SIR,—Mr. Bishop Harman has added to the very great debt which school medical officers already owe him by his recent article on "Standards of vision for scholars and teachers in council schools," published in the JOURNAL of January 13th.

Both from a theoretical and practical standpoint I agree with the scale he lays down for teachers. This is substantially the scale which I have carried out for some years in Bristol. It is perhaps open to question whether six diopters of myopia should be the maximum instead of five, but five is undoubtedly to be preferred. In applying such a scale one of course decides upon each case on its individual merits, after a careful examination of the eyes and also of the general health of the student, allowing a wider latitude in the case of a thoroughly healthy person who lives as far as possible an out-of-door life.

In regard to scholarships, while I agree that the standards laid down by Mr. Harman are theoretically ideal, I do not think that in practice it is possible to enforce so rigid a scale. Many children who obtain scholarships at age 11 have not yet decided upon their future careers, and may or may not take up close work occupations. To refuse to allow such children to hold secondary school scholarships because of a myopia of three diopters, which corrects to 6/6, is, I think, scarcely possible, and I would like to suggest to Mr. Harman that he should reconsider his standards for junior and senior scholarships.

I hope Mr. Harman's valuable article will be widely read. If it is, much trouble which is caused at present by the widely divergent views held by the medical profession on this subject will be saved.—I am, etc.,

R. A. ASKINS, M.D.

Guildhall, Bristol, Feb. 5th.

## INFECTION DURING INCUBATION.

SIR,—The period of school epidemics is again with us, and measles, mumps, and whooping-cough are attacking the children. The general practitioner is constantly asked by anxious parents when a child who has been exposed to infection, and who may be incubating an infectious disease, is safe to mix with other children. It is a difficult question to answer, yet one hesitates to isolate such children at once on account of loss of work and inconvenience. Medical textbooks and the Medical Officers of Schools Association publish the incubation and quarantine periods of the different infectious diseases, but nowhere can I find any statement as to the period of safety during incubation after exposure. The object of this letter is to inquire whether it would not be possible for the Medical Officers of Schools Association or other authority to issue a statement giving the times during which it is safe for a child who has been exposed to infection and may be incubating an infectious disease, to attend school before being isolated. I fully realize that in the case of some infectious diseases, such as scarlet fever, diphtheria, and small-pox, immediate isolation is essential, but in others, such as measles, whooping-cough, German measles, mumps and chicken-pox, there could be no harm in allowing children, who have been exposed to infection to continue attendance at school for a stated period provided their clothes were disinfected. Much inconvenience and loss of work would then be prevented.—I am, etc.,

Woking, Jan. 2<sup>th</sup>,

R. THORNE THORNE.

## THE CAUSE OF A COMMON COLD.

SIR,—The note in the BRITISH MEDICAL JOURNAL, December 30th, 1922, on the cause of the common cold should be widely appreciated. One must look for other factors beside the omnipresent germs.

The symptoms of an acute nasal catarrh appear in the first place to be simply an overaction of a normal reflex. A victim to catarrh constantly asks himself, "Have I caught a fresh cold? Is this a wholesome sneeze, or is there more to follow?" In some subjects any stimulation of the nasal mucous membrane appears to overact, and the reflexes concerned become more and more sensitive and easily provoked; then follows congestion, the blocked nose, hypersecretion, more irritation, and so on. The sensation of cold to any part of the body may start the reflex.

Does not this suggest that the condition of the nervous system, or some part of it which permits reflex action on too slight a stimulation, may be a primary factor in acute nasal catarrh? I recall, thirty years ago, developing a severe cold from one sniff at a fiendish invention called a "smoke ball."

Nature's method of cure appears simple: The mucous membrane swells, smell and perhaps taste is lost, the over-irritated nerve terminals are buried—if one may use the expression—and rested until such time as they can carry on their function without excessive zeal. When the reflexes return to the normal the cold is cured.

Cold *per se* does not provoke a catarrh; no one "catches a cold" in a dry frosty air, but let one enter a warm room after a day on the ice, and the nasal mucous membrane may become congested and the nose blocked in a shorter time than it would take a thermometer to react. Then follows secretion and sneezing.

In very chronic cases of nasal or bronchial catarrh one imagines there must be some permanent enlargement of the smaller vessels from constant engorgement, such as one sees in many throats and the alcoholic nose. The congestion is naturally relieved by hypersecretion, and this, perhaps, is why an antiseptic vaccine, as in my own case, fails to give permanent or any relief. Whatever part germs play—and they can hardly fail to be present—there is no obligation to overlook other factors.—I am, etc.,

Fourisburg, O.F.S.

FRANK ELVY.

MR. MARTINUS NIJHOFF, Lange Voorhout 9, The Hague, has acquired the entire stock of the collected edition of the works of Dr. Beyerinck, professor of bacteriology and microbiology at Delft. There are five volumes, and a set is sold at 40 guilders. The same publisher has also acquired the stock of the jubilee volume presented to Dr. Pekelharing, containing forty papers on physiological subjects, and of similar volumes presented to Lorentz, Onnes, Wiukler, Zwaardemaker, and Jungbunn, an authority on the natural features of Java.

## Obituary.

It is with deep regret that we announce the death of another old member of the British Medical Association, Dr. CHARLES A. FOYL, which occurred from pneumonia at Southport on January 16th. He was a son of the Liverpool harbour master, and, showing symptoms of pulmonary weakness, he was sent to sea as a youth; it was not until he was about 30 years of age that he was considered sufficiently strong to take up the study of medicine, which had always been his wish. He became a student of the Liverpool School, qualified L.R.C.P.S. Edin., L.R.F.P.S. Glasg. in 1893, and settled in Blackpool, where for many years he was a successful and popular practitioner. His chief weakness, however, returned, and he retired from practice to seek health in many places, finally settling in Southport, which seemed to suit him best. He was of a highly sensitive nature and artistic temperament. The former often made the pursuit of his calling anxious and painful, but the latter gave him much consolation, especially in music. He was of a retiring disposition and in later life sought seclusion. But to those who enjoyed his intimacy he was a warm-hearted and thoughtful friend, and among them he seemed happiest in rendering on the piano for their enjoyment the works of his favourite composers. He was 65 years of age. He leaves a widow but no children.

Dr. ALEXANDER HERON, J.P., one of the oldest and most respected and beloved of medical men in Northern Ireland, died on February 1st at his residence, "Greenfield," Katesbridge, near Banbridge. His father and grandfather had been ministers in the district. After obtaining an Arts degree with honours he took the M.D. of the old Queen's University in Ireland in 1866, and set up in "Greenfield," the house in which he had been born, and in which he lived and died. He soon gained a large practice, and in 1882 was appointed coroner for South Down, which post he held till his death, assisted in later years by his son. The numerous warm and sympathetic resolutions that were passed by the many public boards of which he was a member, and the depth of the private grief, all testify to the ability, the kindness, and the upright character of the late Dr. Heron. In his youth he was a keen cricketer, and played against England in the days of Grace. His wife predeceased him a year ago, and he leaves two sons (one is Dr. Heron of Bristol) and a daughter, with all of whom much sympathy is felt.

The announcement of the death, on January 15th, of Mrs. RUTH MARY SLADE, M.B., Belfast, was received with much widespread regret. She had been overworked and developed bronchopneumonia, from which she was slowly recovering, when complications set in under which she sank. Dr. Slade was a daughter of Major S. Craig; she married the Rev. E. H. Hobart Slade, M.A., B.D., Government chaplain in the Punjab, but was early left a widow; she practised massage for a time, but with praiseworthy diligence took the medical course in Queen's University of Belfast, and gained the M.B. in 1919. Starting in Belfast, she gained in a remarkably short time a large practice, and was appointed assistant in the Queen's Street Hospital for Sick Children, then in the Samaritan Hospital for Women, and in the Maternity Hospital; she was also medical officer of the Salvation Army Home at Thorndale. These multifarious duties were too heavy, and no doubt undermined her strength. Dr. Slade was very popular, and her experience in life was of inestimable value to her patients, whose esteem and friendship she won. Much sympathy is felt for her aged father, her young son, and the family.

Dr. ALLAN DOUGLAS LOW, of Bridgend, died on January 28th, aged 43, from septicaemia, following an injury to a finger. He received his medical education at St. Mary's Hospital, London, and took the diplomas of M.R.C.S. Eng. and L.R.C.P. Lond. in 1903. He held a commission as captain in the R.A.M.C. (T.) and during the early days of the war examined a large number of men for military service. Later he served as captain R.A.M.C. in France, and was awarded the Médaille de l'assistance publique en argent in 1918. Dr. Low was surgeon to the Bridgend Cottage Hospital and to the Miss Bennett Charity at Laleston. He was a member of the Cardiff Division of the British Medical Association, and

was recently appointed to the Lord Swansea Physical Training School at Bridgend. He is survived by his widow and two children.

We regret to record the death on February 9th of Dr. CONNOR W. OWEN, at the early age of 50. He was born at Llanfair P.G., Anglesey, and received his medical education at Edinburgh University, where he graduated M.B., C.M. in 1894. After holding the post of assistant medical officer to the North Wales Counties Lunatic Asylum he served as civil surgeon in the South African Field Force. He then started practice at Bangor, and was appointed medical officer to the Bangor Workhouse and Union Infirmary, and public vaccinator for the area. He became honorary physician and radiologist to the Carnarvonshire and Anglesey Infirmary. He was honorary secretary to the North Carnarvon and Anglesey Division of the British Medical Association, 1912-14. He was a keen Volunteer officer, and was called up as combatant officer in the Carnarvonshire and Anglesey Artillery in August, 1914. During training his health completely broke down, and he returned to his practice much debilitated. He was an ardent Freemason and a past-master of the R. Leek Lodge. As a practitioner Dr. Owen was able, generous, and kind. As a colleague he was most straightforward and easy to work with. He will be mourned by his patients and friends, and particularly by his brother practitioners. He leaves a wife and young daughter to mourn his loss.

We regret to record the death, on February 12th, of Dr. EDWIN ARTHUR DANDO of Dudley, at the age of 50. Dr. Dando received his medical education at Birmingham, and took the diplomas of M.R.C.S. Eng. and L.R.C.P. Lond. in 1896. Although he had been in delicate health for some years, he had built up a large practice in Dudley and the surrounding district, where he was highly respected. He was awarded the Edward Medal in 1910 for his remarkable bravery in connexion with a colliery accident. Clad only in pyjamas, Dr. Dando descended a coal mine where a fire had broken out, in order to succour a number of miners who had been overcome by fumes; as a result of his efforts several lives were saved, but his brave act had undoubtedly a permanent ill effect on his health. He was for many years a member of the British Medical Association, and had contributed to the columns of this JOURNAL. He was a bachelor, and is survived by three brothers and three sisters.

We regret to record the death of Dr. BENJAMIN WAITE MACARTHUR, of Golborne, Lancashire. He was educated at Glasgow University, and took the Scottish triple qualification and the D.P.H. in 1883; he graduated M.B., C.M. Glasg. in 1884, and M.D. in 1895. After having been house-surgeon at Glasgow Lock Hospital he went into practice at Golborne, and at the time of his death he was medical officer of health for the district.

THERE was an error in the obituary notice of Professor Röntgen. It was said that the paper announcing his discovery was read in January, 1896; the correct date is December, 1895. A translation of the paper was published in the issue of *Nature* for January 23rd, 1895.

## Universities and Colleges.

### UNIVERSITY OF OXFORD.

At a congregation held on February 17th the degree of Doctor of Medicine (D.M.) was conferred on W. T. Collier, F. G. Hobson, and W. S. Dawson.

### UNIVERSITY OF CAMBRIDGE.

As already announced in this column, the Senate has accepted the offer of the Ministry of Agriculture and Fisheries of a sum of £30,000 to found a chair of animal pathology in the University, with a view to the subsequent establishment of an institute for research in the same subject. The Council of the Senate has now framed regulations to give effect to this decision. It is recommended that the duty of the professor shall be to promote the study of animal pathology by teaching and research, and to act, if required, as director of the institute when that is established. In the first instance he should be elected for five years and then be eligible for re-election. The stipend should be £1,200 per annum, payable out of the funds received from the Ministry of Agriculture, or £1,000 if the professor holds a fellowship or the headship of a college. The site chosen for the headquarters of the proposed institute adjoins the School of Agriculture, the new Biochemical Laboratory, and the Molteno Institute.

It is announced that the managers of the Nita King Research Scholarship, which has been established for the encouragement of original research in the etiology, pathology, and prevention of fevers, will shortly appoint a scholar. The names of candidates should be sent to the Professor of Pathology before March 12th.

At a congregation held on February 16th the following medical degrees were conferred:

M.B., B.Ch.—W. H. W. Cherne.  
B.Ch.—H. G. Oliver.

\* Admitted by proxy.

### UNIVERSITY OF BRISTOL.

THE following candidates have been approved at the examinations indicated:

FINAL M.B., CH.B.—F. J. Hector, \*Marguerite G. Hughes, \*A. J. Keyvil, \*Doris M. Pullen. (Part II, Completing Examination): B. A. Crook, J. M. Evans, Frances M. Jones, J. A. L. Roberts, H. L. Shepherd, H. J. R. Spreadbury, F. K. Wilson. (Part I, including *Forensic Medicine and Toxicology*): S. H. Blacker, A. P. Bodman, E. G. Bradbeer, G. B. Bush, W. L. Cossham, Mary F. Dalton, F. R. Edbrooke, N. J. England, H. M. Golding, W. A. Gornall, J. L. Griffin, R. C. Hateher, A. G. Heron, Doris E. Joscelyne, F. C. Joscelyne, E. F. King, A. H. Marshall, J. R. Nicholson-Lalley, R. A. Sammons, A. E. Sherwell, H. Taylor, R. E. Whitby, Cecil F. Wilson. (Part I only): Naomi J. Bown, Helen M. Dixon, Lorna Dunn, Prosper G. Evans.

D.P.H.—Zaki Khalid.

\* With second class honours.

### UNIVERSITY OF DUBLIN.

#### TRINITY COLLEGE.

At the spring commencements held on Shrove Tuesday, February 13th, the degree of M.D. was conferred upon F. Y. Pratt.

## Medical News.

SIR ARTHUR KEITH, F.R.S., will deliver his six Hunterian lectures on Man's Posture: Its Evolution and Disorders, in the theatre of the Royal College of Surgeons, Lincoln's Inn Fields, on March 5th, 7th, 9th, 12th, 14th, and 16th, at 5 p.m.

On February 19th Dr. Vaillant, the French radiologist, who has lost both arms in the course of his work in X-rays, was entertained at a reception by the Paris Municipal Council in the Hôtel de Ville. Those present included M. Strauss, Minister of Hygiene; the President of the Prefectorial Council of the Seine; the American Ambassador, Mr. Herrick; and Madame Curie. Dr. Vaillant subsequently received at the hands of the American Ambassador the Gold Medal of the Carnegie Foundation in recognition of his services to science.

At the annual special meeting of the Middlesex Hospital Medical Society to be held at the hospital on Tuesday, March 6th, at 8.30 p.m., Dr. J. S. Haldane, F.R.S., will deliver an address, entitled "The Institutes of Medicine and Surgery." Afterwards demonstrations on radiology, electrocardiology, and bacteriology will be given.

WE are informed by the secretary of the governing body that the post of medical officer of the Charterhouse School, at Godalming, Surrey, will be vacant at the end of the summer quarter, and that details of the appointment will be announced later.

THE seventh annual meeting of the Japan national congress of medical practitioners was held at Tokyo on November 17th and 18th, 1922. Dr. Kitasato, president of the association, gave the opening address, on the thesis that the national health would be greatly improved by further scientific investigations. A draft of the law of health insurance, and the results of a Government inquiry on the best methods for decreasing infant mortality, were referred to a special committee.

At the meeting of the Child-Study Society to be held at the Royal Sanitary Institute, 93, Buckingham Palace Road, S.W., on Thursday, March 1st, Professor Leonard Hill, F.R.S., will deliver a lecture on "The Sun and Open-Air School"; the chair will be taken at 6 p.m. by Sir Henry J. Gauvain, M.D.

THE King has appointed Lieut.-Colonel David James Graham, O.B.E., R.A.M.C. (T.A.), to be Surgeon Apothecary to His Majesty's Household at Holyrood Palace, in succession to the late Dr. William Black Alexander.

MR. C. — HOLLAND, Ch.M., honorary medical officer, Eltham Royal Infirmary, Liverpool, will deliver a Thompson Memorial Lecture before the Röntgen Society on Tuesday, May 1st.

THE Right Hon. T. R. Ferens, High Steward of Hull, will be president of the thirty-fourth Congress of the Royal Sanitary Institute, which is to be held in Hull at the end of next July.

THE French Government continues to show its interest in the dissemination of information with regard to spas and health resorts of France, which is very rich both in climatic stations and mineral waters. Formerly these stations, with the exception of a few, were not so well organized as those of Austria and Germany, but great improvements have been made and others are in progress at those places which used to be backward. There is now published a fortnightly paper called *La Presse Thermale et Climatique*, which has taken the place of the older *Gazette des Eaux*. It contains papers on hydrotherapy and news of use to doctors in this country. Further particulars can be obtained on application to the French Touring Office at 56, Haymarket, London, S.W.1, which also issues a monthly *Bulletin* for the use of tourists in France.

In celebration of their golden wedding Dr. and Mrs. Hedley, of Middlesbrough, have been presented with a reproduction of an early eighteenth century gold vase by the members of the medical profession of Middlesbrough and district.

At a sessional meeting of the Royal Sanitary Institute in Sheffield on March 2nd and 3rd Professor E. Mellanby, M.D., will open a discussion on the prevention of disease by feeding. There will also be a discussion on extraneous matters in food, introduced by Mr. J. Evans, city analyst.

THE late Emeritus Professor A. Crum Brown of Edinburgh, who left £8,543, bequeathed to the Royal Society of Edinburgh his portrait, painted by Mr. E. A. Walton, presented to him by friends and former pupils. He made provision also for handing over his collection of portraits of scientific men in part to the Department of Chemistry of Edinburgh University and in part among his former assistants. His theological, religious, and philosophical books were bequeathed to the libraries of the colleges of the United Free Church and his scientific books to the University of Edinburgh.

THE Burrow Hill Colony, Frimley, Surrey, which has recently been opened under the auspices of the National Association for the Prevention of Tuberculosis, has received a donation of £50 from the King. In the sanatorium section of the colony, which consists of twenty beds, vacancies occur from time to time, and suitable cases are admitted on the recommendation of local authorities and private practitioners at a weekly charge of fifty shillings. Further information may be obtained from the National Association for the Prevention of Tuberculosis, 20, Hanover Square, London, W.1.

A FOURTH edition of Sir J. H. Parsons's *Diseases of the Eye* will be published shortly by Messrs. Churchill. It has been revised, some new coloured plates have been introduced, and a section on preventive ophthalmology has been added. The same publishers announce the early publication of *Practical Midwifery* by Dr. Gibbon FitzGibbon, the Master of the Rotunda Hospital.

THE proposal to change the name of the London County Westminster and Parr's Bank to "Westminster Bank Limited" was finally approved last week, and the bank will be known by its new name on and after March 1st.

Messrs. BOWES AND BOWES (1, Trinity Street, Cambridge) have issued a catalogue of books they have for sale from an important botanical library, and of other books and periodicals in other sciences, including medicine.

THE Dean of the Paris Faculty of Medicine has been authorized to accept a gift of 50,000 francs from Madame de Rothschild, the annual interest from which will be given to poor students, preferably Jews, of the Faculty of Medicine.

COSTER and HEVEY, continuing their researches on the element 72, have reported in *Nature* that they have investigated a great number of zirconium minerals from different parts of the world, and that they all contained from 5 to 10 per cent. of the new element. They have also found it in as high a percentage as 5 in commercial zirconium oxide. Further, by a chemical method they have obtained several grams of a substance in which the presence of about 50 per cent. of hafnium could be established. On the other hand, Urbain and Dauvillier, in a letter in our contemporary last week, state that they regard the element found by Coster and Hevey as identical with an element which they had already found and named "celtium." In 1911 Urbain detected two rays in the residue from a rare earth, which he held indicated the existence of an element hitherto unknown; in papers presented to the Académie des Sciences last May Urbain and Dauvillier reported confirmatory evidence. They claim to be the discoverers of the element 72 and therefore entitled to name it. It will be remembered that Dr. Alexander Scott, F.R.S., had reported to the Chemical Society that he had obtained an oxide of the new element from certain black sand obtained from New Zealand and that he had sent samples to Coster and Hevey for x-ray examination. He now states that the Copenhagen observers have failed to detect the presence of hafnium in these samples.

PROFESSOR DEPAGE has been elected president of the Brussels Faculty of Medicine.

THE spring intensive course of the North-East London Post-Graduate College at the Prince of Wales's General Hospital will begin on March 12th, and will last for fourteen days. It will include lectures and demonstrations of clinical methods and cases, and work in the general wards and special departments of the hospital.

IT is intended to have an exhibit representing thermal establishments, medicinal baths, and sanatoriums at the British Empire Exhibition in 1924, and the civic authorities of such towns as Bath, Harrogate, Leamington, Malvern, Tunbridge Wells, and Droitwich have been invited to co-operate. In the tropical diseases section it is hoped to illustrate all the important diseases of tropical countries.

A NEW organization to promote the social, ethical, and financial interests of the medical profession, the Sindicato de Médicos, has been formed in the Argentine, with its headquarters at Buenos Aires. It publishes a journal entitled the *Bulletin*, and already a quarter of the medical practitioners in the Argentine have enrolled in the association.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

The postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY and BUSINESS MANAGER (advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL phone, 2630, Ger Medical Associa *Bacillus*, Dublin 6, Rutland Squ telephone, 4361, Central.

## QUERIES AND ANSWERS.

### INCOME TAX.

"SCALPEL" is paying interest on money borrowed for the purchase of a practice. He asks if he can treat the interest as an expense for tax purposes. Also, what expenses can he deduct against an assessment under Schedule E on a parish appointment?

\* 1. If the interest is payable to a bank it can be treated as a professional expense; otherwise, tax is deductible at the full rate from the interest as and when it is paid, and in those circumstances the interest cannot be deducted but must form part of the profits on which tax is paid—for example:

Amount of interest	£50
Average profits after deducting interest	£1,000

The amount of the assessment must include the interest—say £40 on the average; the practitioner pays tax on £1,040, but recoups himself by deducting tax from the interest.

2. We understand that the Board of Inland Revenue acquiesces in the usual method of assessment in such cases, which is for a single charge to be made under Schedule D on the full income of the practice—that is, bringing in the emoluments of the appointment as receipts and deducting all proper expenses. Where this is not done, the person assessed should deduct under Schedule E such (apportioned) expenses as are incurred wholly, exclusively, and necessarily in performing the duties, and claim the balance of the total expenses of the year under Schedule D.

"H. W. F." sold his old car in 1918 and bought another to replace it in 1922. The local inspector refuses to allow a deduction for the cost "as the selling of the old car and the buying of the new did not take place in the same year."

\* We think that the inspector's attitude is incorrect. A certain expense was incurred in 1922 and the question to be decided is whether, and if so to what extent, it included capital expenditure. To decide that question all the facts must be considered and there seems to be no justification for shutting out of

# A Lecture ON THE FUNDAMENTAL CONCEPTIONS OF BIOLOGY.

DELIVERED AT KING'S COLLEGE, LONDON,

BY

J. S. HALDANE, M.D., LL.D., F.R.S.,  
OXFORD.

BIOLOGY is the branch of natural science which deals with life; and the question which will be discussed in this lecture is whether we are compelled, in dealing scientifically with the phenomena of life, to make use of any fundamental conception or axiom which differentiates biology from other branches of science. I shall endeavour to show that the answer to this question must be an affirmative one if we are to bring together a coherent and progressively developing body of knowledge relating to the phenomena of life. In other words, I shall try to show that biology is, or ought to be, an independent science.

There is at present little difficulty in distinguishing practically between what we call phenomena of life and what we call inorganic phenomena. But as to the nature of the distinction, and whether it is in any real sense fundamental, there has been no agreement. I shall first glance at the opinions which have been held on this subject in modern times, and the objections to these opinions.

## *The Mechanistic Theory of Life.*

In the writings of Descartes, and particularly in his *De Homine* and *De Formatione Foetus*, we first find quite clearly expressed the doctrine that a living body is simply a piece of physical and chemical mechanism, produced by a mechanical process of development. He describes in detail, and with great clearness, the manner in which he believed that the machinery of a living animal works or may work, and the mechanical process by which this machinery is, or may be, formed in the embryo. Although it soon appeared that most of his details were entirely wrong, his belief that physiological processes are in ultimate analysis nothing but what may, broadly speaking, be called mechanical processes has survived, and at present represents the opinion which is generally regarded as orthodox in biology. Not only biologists, but also the general public, speak of the mechanism of the living body and of all the processes occurring in it. They even regard it as self-evident that, apart from conscious action, everything occurring in a living organism is mechanically determined. I cannot, therefore, pretend that my own conclusions on this subject are other than heretical for the present.

Descartes himself was no materialist. For him the soul was independent of the body; but as to how body and soul interact his account is far from clear, and on this point his successors took divergent views. It is interesting to remark that the extremest mechanistic theories of life have often been combined with the most orthodox theological opinions as to body and soul. To realize this we have only to glance through Paley's *Evidences*, or to remember that Theodore Schwann, though he was a leader of the modern mechanistic school in physiology, was also a devout and orthodox Catholic.

## *Animists and Vitalists.*

The mechanistic conception of life, as put forward by Descartes, was only accepted by a minority of the biologists of his time, and was specially attacked by Stahl, the author of the phlogiston theory in chemistry. Stahl was so impressed by the apparent purposive character of physiological processes that he concluded that the soul acts directly at all parts of the body, though we may not be conscious of this action. For him, therefore, life was a process guided by the soul, and distinguished from inorganic processes by this fact. Stahl's teaching is known as animism, and the best known avowed modern representative of animism is Professor McDougall, whose well known book, *Body and Mind*, is a defence of this doctrine.

The majority of biologists in the eighteenth and first half of the nineteenth centuries followed neither Descartes nor Stahl, but took what may be described as a middle course. Since there is no consciousness of apparently purposive phenomena such as assimilation, growth, and reproduction,

these were attributed to an influence called the vital principle or vital force, which was conceived as something midway in character between the conscious soul and mechanism, and involved no such strained theory as that plants possess souls. On the other hand, mechanical explanation was adopted in all cases where it seemed capable of adoption. The boundary line between the action of vital force and mere mechanism was a shadowy one; but this dualistic system of explanation held its ground for long. The great comparative anatomist and physiologist Johannes Müller may be regarded as a typical representative of it as it existed last century. Liebig and Wöhler were other well known representatives.

## *The Neo-Mechanists of Last Century.*

About the middle of last century the younger physiologists became altogether dissatisfied with the conception of vital force, and at the same time believed that they were finding a way towards dispensing with it altogether. Schwann, for instance, after discovering what is now familiar to us as the cellular composition of the bodies of higher animals, believed that he had also discovered that cell formation is only a form of precipitation. Mayer applied his new conceptions of energy to the living body, and pointed out that oxidation of food material is the source of the energy of muscular contraction. On all hands the younger biologists put forward mechanical theories of what had hitherto been attributed to the influence of vital force. The conception itself of vital force was also vigorously attacked, and the attack was a deadly one—not one whit the less so though most of the new mechanistic explanations of that time turned out to be wrong, like Schwann's theory of cell formation.

It was pointed out by the neo-mechanists that all manifestations of life are found to depend on physical and chemical conditions in the environment. There is thus no evidence whatever for the existence of an influence which is independent of physical and chemical conditions, as the vital force was assumed to be. All vital phenomena are dependent on such factors as the presence of oxygen, water, various mineral constituents, warmth or light, and suitable stimuli of various kinds. The more closely we investigate, the more certainly does this appear; and for this reason biologists will never go back to vitalism or animism.

It is true that there are still professed vitalists, among whom the best known is Driesch. He bases his vitalism especially on some of the facts revealed by experimental embryology, and particularly on his discovery that when the cells of an early developing embryo are separated from one another complete embryos may nevertheless be developed from each of the separated cells. A guiding influence seems, therefore, to be present in each cell, independently of the arrangement and amount of the material which was present in the original ovum. This guiding influence appears to cause each cell to behave in such a way as to contribute towards forming a complete embryo in spite of such confusion as is produced by artificially separating the cells. In reality, however, there is nothing to show that the behaviour of each cell is not a response to influences in its environment. When the cells are separated these influences must be changed. When they are left together each cell will influence its neighbour cells, stimulating or inhibiting their development in different directions, with the result that the embryo as a whole develops in the usual way. In the behaviour of the cells in a developing embryo there is therefore nothing fundamentally different from the responses to stimuli which we observe in any living structure. We can investigate these stimuli and the corresponding responses; and when our method is delicate enough we can always discover their connexion. Biology has no use for the vitalistic assumption of an internal guiding influence which is independent of the influence of external conditions. Such an assumption is only an artificial hindrance to investigation, and amounts to an attempt to strangle it.

## *Failure of the Neo-Mechanists.*

In so far as the mechanistic movement which culminated about the middle of last century was a casting out of vitalism from biology I do not think there is anything further to be said. Nevertheless it seems to me that the coincident attempt to establish biology on a mechanistic basis has been a gigantic failure. It is one thing to conclude that the structure and activity of any living organism or part of it is dependent on its environment, but quite another thing to draw the additional conclusion that life must be a mechanical process, and can be investigated successfully on this assumption.

The usefulness within certain limits of mechanical explanations in physiology is, of course, evident, and was equally evident to the vitalists with their dualistic system of explanation. If we skim over the surface of physiology we can represent the life of any organism as if it were a series of mechanical processes such as the working of joints, the ingestion of oxygen into the lungs and blood, or of food material into the alimentary canal and blood, or the formation of images on the retina. Taken separately, each of these mechanical representations is in more or less close accordance with experience, and is correspondingly useful. Nevertheless it was the failure of attempts to extend mechanical conceptions to the phenomena of unconscious life as a whole that gave rise to vitalism; and it is quite evident now that the physiologists of the middle and later parts of last century were altogether mistaken in supposing that they were getting over this failure. The mere abolition of vitalism has in reality left physiology as an incoherent collection of details, with not even the very unsatisfactory vitalistic theory to produce some appearance of unity. The mechanistic cement which seemed so promising fifty or sixty years ago has crumbled away.

To understand this situation it is absolutely necessary to consider closely the characteristic phenomena of life. The outstanding feature which distinguishes what we call the phenomena of life from what we call inorganic phenomena is that in the case of life the form, size, properties, composition, and activity of each part of an organism and its immediate environment depend, broadly speaking, on its relations to the other parts, and that the relationship is actively maintained or reproduced in successive generations. Life is continuous from generation to generation, as was finally shown by Pasteur's famous investigations.

#### *Internal Environment.*

The specific character of each variety of organism and its mode of life have been thoroughly realized ever since animals and plants began to be classified. What has not been realized, however, is that not only are the form and activities of organic structure specific, but also its immediate environment. This feature of life is emphasized in my recently published book *Respiration*; but I wish to place before you in a broader manner the facts relating to immediate environment.

Pasteur's great contemporary, Claude Bernard, was the first to recognize the fact that in the higher organisms the living tissue elements live in an internal environment of a specific character, which is kept relatively constant by the combined activities of the various parts of the body. My own experimental work as a physiologist has been mainly in the development and extension of this conclusion. The tissue elements, for instance, are in relation with the external air through the process of respiration. If, now, we examine this relation we find that the concentration of carbon dioxide and oxygen in the air contained in the alveoli or air cells of the lung remains extraordinarily constant, particularly as regards the percentage of carbon dioxide. This is brought about by regulation of the breathing in accordance with the very variable amounts of carbon dioxide formed in the muscles or elsewhere and carried by the blood to the lungs, or also present in the outside air. Hence the concentration of carbon dioxide in the arterial blood is kept extremely steady, and the delicacy of this regulation is extraordinary. Carbon dioxide when in solution acts as a weak acid, and further investigation showed that what is regulated is not the mere amount of carbon dioxide in the blood, but its reaction or hydrogen ion concentration. This regulation of reaction is so delicate that not even the most sensitive of the available methods of measurement can follow it exactly.

The regulation of the oxygen concentration in the alveolar air is not nearly so delicate; but if we consider, not merely this oxygen concentration, but the percentage saturation with this oxygen of the haemoglobin in the arterial blood, we find an almost equal delicacy of regulation. We have also every reason to believe that if we considered the reaction and partial pressure of oxygen, not merely in the arterial blood, but in the liquid bathing the tissue elements in the central nervous system, we should find a still greater accuracy of regulation, since the rate of blood flow is, in general, regulated in such a manner as to keep the reaction and oxygen pressure steady in spite of great local variation in consumption of oxygen and formation of carbon dioxide. Let us now pass to the physiology of the kidneys. In this part of physiology recent advances have been almost as striking as in connexion with respiration. Within the last

few years it has become increasingly evident that renal excretion regulates the composition of the blood with a delicacy even greater than that connected with intake and output of gases by the lungs. To the smallest excess or deficiency of water or of chloride in the blood the kidneys react by greater or less excretion of water or chloride. To the minutest excess or deficiency in alkalinity they react similarly with a far greater excretion of alkali or acid. To excess in the percentage of sugar in the blood they react by excreting an enormously greater percentage of sugar in the urine. To minute percentages of urea and numerous other substances they react by concentrating them into the urine. By this selective action they keep the composition of the blood normal in a number of different respects and thus keep the specific internal environment steady.

When we look to what is known of other organs or parts of the body we find similar regulative activity. The influence of the liver in regulating the percentage of sugar in the blood was discovered by Claude Bernard himself, and every year adds to our knowledge of the regulative action of different organs and tissues. Perhaps the simplest case is that of the fat-storing tissues so widely distributed in animals and plants.

I have said enough to show that in higher organisms the maintenance of the immediate environment is just as striking a phenomenon as the maintenance of what we regard as the actually living structure. Is there any real difference in this respect, except in degree, between higher and lower organisms? I do not for a moment believe that there is, although in the case of lower organisms, and particularly unicellular organisms, it is difficult to obtain the clear evidence that we can easily obtain from the study of higher organisms, and particularly from the physiological study of man. In the case of unicellular organisms, or single cells of man, we are apt to assume that what has been called by the convenient but very misleading term "protoplasm" represents living structure, while anything outside the delicate cell wall represents environment. But all the probabilities are against this view. We have every reason to believe that within living cells the specific structural elements have an internal environment similar in function to the definitely known internal environment of higher compound organisms. There seems, for instance, to be little doubt that the contractile vacuoles present in fresh-water unicellular organisms are constantly engaged in excreting and pumping out the excess of water which leaks in through the semi-permeable cell wall in virtue of the higher "osmotic pressure" in the internal medium. The vacuoles are thus constantly performing the same function as the kidneys during the excretion of any excess of water that has been taken into the internal medium of a mammal.

#### *Internal Nervous Environment.*

It may appear at first sight as if the central nervous system is directly exposed through the sensory nerves to the full brunt of physical changes in the external environment, without the intervention of anything corresponding to an internal environment. In the case of any particular kind of sensory excitation we have, however, an automatic physiological raising or lowering of the threshold of excitation in accordance with the total strength of stimulus. This fact appears as the well known law of sensory excitation formulated by Weber. A light-stimulus which produces marked light-excitation with a dim general illumination may produce no excitation at all with a less dim general illumination. For instance, the light-stimulus of a bright star, which produces no excitation at all in even fading daylight, has a marked excitatory effect in the far dimmer illumination of night. Within very wide limits the unit of light-stimulus required to produce excitation varies with the general illumination of the visual field, so that the general excitation remains constant. Moreover, if all the light-stimulus is cut off there is still general excitation of the visual field. In perfect darkness an illuminated field of subjective vision still remains.

We can thus compare the general constancy of the field of sensory excitation with the general constancy of the internal environment. In different parts of the circulatory system and round different cells there are very distinct differences in the internal environment, just as there are very distinct differences in different parts of the visual field. But these differences are extremely small in comparison with differences in the external environment, since they are controlled physiologically.

It is the physiological activities of the living tissue elements that regulate the internal environment and the fields of

sensory excitation. On the other hand, however, the evidence is no less clear that not only the normal activity of the living tissues, but also their normal structural maintenance, depends on the maintenance of the internal environment. For instance, not merely abnormal function, or cessation of function, results from imperfect regulative action of the lungs or kidneys, but also grave changes in structure. Analysis of the symptoms met with in disease of different organs, or in connexion with such great abnormalities of external environment that the compensatory resources of the body are overpowered, is constantly teaching this lesson in different directions. The question whether living structure determines environment, or environment determines living structure, is thus not one that can be answered. If we say that they act mutually on one another this is no answer: for apart from their active relationship they cease to exist except in the totally changed form of dead or dying material. Both living structure and internal environment are expressions of molecular and ionic flux. If the flux is interfered with both structure and environment are rapidly changed. Living structure and its immediate environment are not things which can be separated from one another like lifeless things which we regard as mutually acting on one another. In other words, the conception itself of mutual interaction is not applicable.

Organisms will continue to live in very different external environments; but this is only because they are still capable of maintaining their internal environment. The higher organisms are capable of doing this to a very marked extent, and this is one of their distinguishing characters.

#### *Structure, Environment, and Activity.*

The environments of the individual cells in any tissue or organ are not merely a general internal environment common to all the cells, but special environments dependent on the influence of neighbouring cells, and even of cells in distant organs, such as ductless glands or sexual organs. The effects of interference with either these special environments, or the general internal environment, are seen in the cell changes studied by pathological anatomists. It is on the special environments which establish themselves round individual cells that the specific structures of organs and tissues must ultimately depend. But on the other hand these specific environments depend on the activities of the cells themselves, just as does the general internal environment. Here again structure depends on environment and environment on structure; and if we attempt to separate living structure from its active environment we simply fail. Form, composition, activity, and environment are inseparably bound up together. They only exist relatively to one another. In biology relativity is no far-off principle behind ordinary observation. It confronts us at every turn when we attempt to express life as a mechanical process of interaction between organic structure and environment, or between cell and cell.

This relativity is the rock on which all past attempts to frame a mechanistic conception of life have foundered, and on which all future attempts will certainly founder. The gross external changes in which life manifests itself can be expressed in physical and chemical terms. But when we endeavour to express in similar terms the processes by which these changes are actuated and regulated we are everywhere baffled by an indefiniteness and complexity due to the fact that each phenomenon, whether of apparent structure or apparent activity, is relative to other phenomena. Instead of definite structural machinery such as Descartes or the neo-mechanists of last century imagined, we seem to find only that unstable and physically indefinite something which we call protoplasm.

If we nevertheless assume that definite though invisible structural machinery exists in all living cells and explains mechanically all the delicate and intensely specific reactions which we discover in living cells, we are at once faced by an insuperable difficulty. All of this assumed structural machinery must have developed in the development of the organism, and must have originated from a very minute part of the structural machinery of the parent organism or organisms. We are thus compelled to assume that in each germ of a future organism there is machinery for the building up of the machinery of the future adult organism, and the building up of this reproductive machinery itself has then to be accounted for, and of the machinery which built it up in previous generations *ad infinitum*.

The mechanistic theory of life involves us, therefore, in

meaningless absurdities. It is evident also that even where we can, as in the case, say, of the working of a joint, lay our hands on a piece of what seems to be definite anatomical machinery, we are equally involved in meaningless absurdities if we attempt to account on mechanistic principles for the reproduction of the joint in successive generations. If, moreover, we try to account on mechanistic principles for the physiological maintenance of the anatomical machinery, we are again faced by the relativity of the phenomena we are dealing with. The more we discover of apparent mechanism in a living organism, and the more delicate and complex this mechanism is, the more hopeless are the problems which face a mechanistic theory of life in connexion with the phenomena of maintenance and reproduction. The discovery of what we call mechanisms in connexion with the phenomena of life is never any advance towards a mechanistic conception of life, since the more of such apparent mechanisms we discover the more completely unintelligible from a mechanistic standpoint does their maintenance and reproduction appear.

To me it seems perfectly evident that not only the vitalistic, but also the mechanistic conception of life is totally unsatisfactory. The mechanists pointed out clearly the impossibility of vitalism, but they failed to see, at the same time, that their own conception of life was equally impossible. With either a vitalistic or a mechanistic conception biology is nothing but chaos. The mechanists are in reality always being driven back on vitalistic ideas to help out their mechanistic conception, just as the vitalists were always using mechanistic ideas to help out their vitalism. But this compromise only conceals, and in reality does nothing to obviate, the chaotic position on either conception. I have tried to analyse the reasons for this unsatisfactory position, and I shall now try to point out what seems to me the only way of escape from it.

#### *Relativity and Persistent Wholeness in the Phenomena of Life.*

As was so clearly pointed out in the opening lecture of this series by Professor Whitehead, the present generation has been witnessing a definite break-up in the fundamental mathematical and physical conceptions which we have inherited through Euclid, Galileo, and Newton. We can, however, still use the Euclidean, Galilean, and Newtonian working hypotheses for nearly all practical purposes in connexion with the mathematical and physical sciences, though their ultimate authority has disappeared. In connexion with the phenomena of life, however, we are everywhere in practical contact with the relativity to one another of the phenomena we are studying, as I have already pointed out. It seems to me, therefore, that in biology it is necessary to abandon, even for ordinary practical purposes, the Galilean or mechanistic conception of phenomena, and frankly embody the principle of relativity in our fundamental working conception. When we take this step we must take care, however, not straightway to introduce confusion by returning in part to the Galilean mechanistic conceptions which Descartes attempted to apply in biology. We must, in other words, treat the phenomena of life entirely from the biological standpoint, and not from that of the Galilean physics.

From the biological standpoint organism and biological environment, structure and activity of structure, parts and other parts, are not things separable in thought from one another, but existing only in their relations. If we attempt to separate them from one another they become from the biological standpoint just as meaningless as is motion or passage of time in an empty universe. Completely separated structural elements are, or at least seem to be, no longer alive, and have thus passed out of the ken of biology, where biologists can meanwhile leave them to the discussions between the new and the old physicists.

When we have admitted that the phenomena of life must be regarded as existing relatively to one another we have only taken a first step in defining a satisfactory conception of life. We have to take into consideration the further fact that life is persistent and continuous from generation to generation. The life of any species of organism is no mere fleeting appearance, but persists in all its essential characteristics. This persistence is also prominent in the life of the individual organism, and the parts of biology which we ordinarily call physiology and anatomy are based on the fact of this persistence. The structure, activities, and internal environment of the individual organism persist, and but for this a scientific treatment of anatomy and physiology would

be impossible. It is not merely relativity, but a definite and enduring order showing itself in the related phenomena, that biology deals with.

At this point I wish to emphasize once more the fact that biology does not begin with living structure, but includes environment. Moreover, there is no sharp distinction between an internal environment under organic control and the external environment. We see this clearly in the case of the air in the lung alveoli; and the same thing is also more or less clear in the case of the contents of the intestine or the temperature of the skin. Each organism, moreover, has its own special "habitat," and either by movements or in various other ways the influence on it of its environment is controlled biologically. It is a difference in the point of view from which we are compelled to regard biological phenomena, and not any spatial boundary, that separates them from what we distinguish as inorganic phenomena. The environment is not something outside of life and acting on it from without. Nor is life something localized within the living structure of an organism. Life is an organic whole without spatial boundaries, and hence cannot be localized definitely. What we can localize in relation to one another are only its manifestations, such as special organic structures or aspects of living activity. There is no more warrant for localizing life within the structure of an organism than for localizing consciousness in the brain.

If we attempt to resolve the life of an organism into a number of separate processes we reach no intelligible result. Nature laughs at us, just as she laughed at Michelson and Morley when they innocently attempted to measure the absolute velocity at which our planet is travelling. If, for instance, we continue to ask by what special pieces of machinery the kidneys or respiratory centre regulate the composition of the blood Nature will continue to mock us until we understand that such questions are meaningless. But if we ask her the sort of questions about the details of renal or respiratory regulation that scientific biology can put she answers us fully. These questions must be asked from the standpoint of the life of the body as a whole, as it is only from this standpoint that an answer can be looked for.

Since the time of the mechanistic movement in biology last century it has been generally taken for granted by physiologists that in the investigation of life all considerations of a so-called teleological character must be left out of account; and this assumption has in every direction fettered and misled investigators. The life of any organism persists as a whole. Both the persistence and the wholeness are just parts of the essential nature of life; and biology seeks out the details of structure and activity in which both the persistence and the wholeness of life manifest themselves. To the mechanistic biologists the appearance of wholeness in the life of an organism seemed to be only superficial. They allowed themselves to be overwhelmed intellectually by the Galilean ideas of the physical sciences; and this diverted them from the proper lines of biological investigation into vain quests for imaginary mechanisms.

The wholeness in the phenomena of life is not merely externally imposed, as in the case of a machine; and if we neglect the inherent element of wholeness we are also neglecting life itself. To bring into clear relief the elements of wholeness and persistence we have only to disturb in various directions the ordinary working or structure of the body. It will then be seen that the normal state soon asserts itself. The organism adapts itself to the new conditions; and life is in reality a constant process of adaptation to varying conditions of external environment. By studying the responses of the ordinary working of respiration, of circulation, of blood composition, of excretion, of the nervous system, and of every other organ and tissue in the body, to changes in environment, we can discover how each organ or tissue plays its part in life as a whole; but if we are out of account life as a whole because this consideration savours of teleology, we reach nothing but an unintelligible jumble of unconnected observations. On this point I emphatically mean what I say.

#### *The Relations of Organisms to One Another.*

In the relations of organisms to one another, no less than in the relations of organism to environment, the wholeness of life is apparent. When Schleiden and Schwann discovered that all the higher organisms are compound it seemed at first as if the life of a compound organism could be resolved into the sum of the lives of the constituent cells. It is very evident now, however, that this would be a very misleading conclusion. The behaviour and structure of individual cells is very

different according as they are normally related to one another as in a compound organism or isolated as in a tissue culture. The behaviour of each cell in the compound organism depends on its specific environment there, which depends in turn on relations to the other cells and their environments. But, as already seen, we cannot, either in deed or thought, separate living structure from its environment. We cannot add up in a sum units which do not exist separately. Hence the life of a compound organism is no mere sum of the lives of its constituent cells.

When we consider the lives of separate organisms, whether compound or unicellular, similar considerations come in. The individuals of a species live and die in biological relation to the lives of one another and of members of other species, just as do the cells in a compound organism.

In accordance with the reasoning which has just been set before you physiology deals essentially, not with illusory quests after the mechanisms of different bodily activities, but with the particular manner in which each structural element plays its part in the life of the organism as a whole. To take an example: it is, and always has been, a vain quest to discover the mechanism of secretion by the kidneys. We can trace the complete failure of such attempts from the time of Descartes onwards through Ludwig and others to the present day. But our physiological knowledge of what the kidneys are actually doing in relation to the maintenance of the life of the body as a whole has steadily grown, and perhaps never so rapidly as during the last few years. It is the same with regard to respiration, circulation, nervous activity, and all other bodily activities. If we try to understand them from the point of view of ordinary physics and chemistry they appear as a chaotic tangle, becoming more chaotic with every advance in detailed knowledge; but from the distinctively biological standpoint which I have tried to present our knowledge of them is both coherent and steadily progressive.

#### *The Future of Anatomy.*

According to the conception which was popularized in the latter part of last century anatomy deals with the structural mechanism of organisms, and physiology with its working. This conception harmonized with the popular Galilean conceptions of the universe, and therefore appealed to what one may call "the masses," but left anatomy high and dry as soon as it became evident that with neither the scalpel nor microscope as applied to dead organisms could structure be found that was capable of throwing light on any fundamental physiological activity. The physiologists got the living organisms, and with them the living parts of biological science. In reality there ought to be no separation between anatomy and physiology except as regards technical methods of investigation. They both deal with the manifestations of life as such. Whether, in the investigation of life, use is made of the scalpel or microscope, or of other physical apparatus, or of chemical methods of different kinds, it is life that a biologist is investigating; and those who allow life to be banished from their mental vision by the nature of the technical methods they employ have no claim to be regarded as biologists. The details which their several methods reveal must be interpreted biologically or else remain outside the scope of biology as a science. The future anatomy will certainly be an experimental science, and will investigate structure as relative to environment and activity.

#### *Conclusions.*

The outcome of this discussion is that biology and the physical sciences are distinct from one another, not because they deal with spatially distinct parts of our world, but because they employ different working conceptions or axioms in interpreting their data. Relativity and persistence of a definite order in the related phenomena are of the essence of the conception of life, while they do not enter into the Galilean conception of the physical universe. Behind this Galilean conception, however, something strangely akin to the biological conception is now beginning to loom up. In addition to the conclusions of Einstein, the new conceptions, evolved by Rutherford and Nils Bohr, of what an atom is, seem to be bringing the physicists into touch with biological conceptions. In any case biology will never rest until biological conceptions have been extended to what is at present interpreted as the inorganic world. The well-meant attempt of the last generations of biologists to treat life as mechanism—in other words, to apply Galilean conceptions to life—has not only been an actual failure, but, if the reasoning

I have placed before you is correct, could not possibly be anything but a failure. In other words, the Galilean conception of the universe, since it cannot represent life, cannot possibly represent reality itself, but is only a preliminary and definitely insufficient working hypothesis with regard to reality. This universe is no disorderly spectacle of independent and self-existent things scattered about indiscriminately in infinite space and time. The facts of biology, even taken by themselves, render any such hypothesis impossible.

I chose the subject of this lecture because it seemed to me of the greatest importance at the present time that we should begin to realize more clearly that what we perceive is a matter of interpretation, and depends upon the axioms or working hypotheses which we adopt as consistent with our observations. In the distinction between biology and the physical sciences this fact comes definitely before us. Biological interpretation occupies a position midway between the Galilean interpretation and humanistic or spiritual interpretations. From the thorough-going Galilean standpoint of materialism the spiritual interpretation is mere illusion, and biology as a science independent of the physical sciences is non-existent. But the time has now come for examination of our axioms and a strict inquiry as to how far they are valid and consistent with experience.

In the course of this examination the spiritual interpretation as the supreme interpretation of our universe is coming again to its own, and a fundamental step seems to me to be the inquiry into the difference between the axioms of biology and those of the physical sciences. Had it been the case that the Galilean conceptions of the physical sciences applied to the phenomena of life the difficulties of a spiritual interpretation of our ordinary experience would have been very great. Biological interpretation provides us with a bridge towards psychological or spiritual interpretation.

Biology does not attempt to deal with distinctively psychological phenomena, although in connexion with the physiology of the nervous system it quite legitimately utilizes conscious responses as a more index of physiological responses, while not attempting to take into account the distinctive characters of conscious responses as such. Hence biology is distinct from psychology. On the other hand, as I have tried to show, the attempts to extend mechanistic conceptions to life have only resulted in proving definitely that the phenomena of life must be interpreted in terms of the distinctive conception of life. For these reasons biology must be regarded as an independent science; and this is the thesis which I set out to establish.

## THE LATE RESULTS OF MENINGEAL HAEMORRHAGE OF THE NEWLY BORN.

BY  
HECTOR CHARLES CAMERON, M.A., M.D., F.R.C.P.,  
PHYSICIAN IN CHARGE OF THE CHILDREN'S DEPARTMENT,

AND

A. A. OSMAN, M.R.C.S., L.R.C.P.,  
CHIEF CLINICAL ASSISTANT IN THE CHILDREN'S DEPARTMENT,  
GUY'S HOSPITAL.

Or cases which present themselves in later childhood as examples of infantile cerebral diplegia or paraplegia, dating from birth, what proportion owe their origin to meningeal haemorrhage occurring during or shortly after the moment of birth? It is a question which has often been asked and to which very different answers have been given. Sixty years ago Little, the orthopaedic surgeon, had made up his mind that the majority of the children brought to him with spastic paralysis owed their unfortunate condition to accidents occurring at birth. So impressed was he with the truth and importance of this discovery that, introduced as a guest, he attended a meeting of the Obstetric Society of London and read a paper, thereafter famous, in which he invited the co-operation of his obstetric friends in investigating the origin of these disturbances, with the later results of which he was familiar and which he described graphically and with singular completeness.

The response to his appeal was apparently somewhat disappointing. The discussion which followed was meagre and barren. The distinguished obstetricians present had no knowledge of these unfortunate results of their ministrations. It was not until the year 1885 that a definite investigation

was undertaken by Sarah MacNutt.<sup>2</sup> In ten infants dying at birth or soon after birth, with symptoms of asphyxia, stupor, paralysis, rigidity, and convulsions, she demonstrated the presence of extensive meningeal haemorrhage below or above the tentorium cerebelli or in both situations. Gowers<sup>3</sup> unhesitatingly accepted the views of Little and MacNutt as in accord with his own extensive experience and describes cases with symptoms similar to those of Little under the name "infantile meningeal haemorrhage." Of MacNutt's work he is reported as saying, "It is by far the most valuable contribution to medical science that the profession has yet received from members of her sex."

In 1889 Osler<sup>4</sup> published his book *The Cerebral Palsies of Children*. He adopts and adduces evidence in favour of the views of Little and Gowers.

"Facts have gradually been accumulated to show that haemorrhage, usually meningeal, is a very frequent condition in children dying shortly after birth of asphyxia or convulsions, and as the birth palsies almost invariably have this history it seems reasonable to conclude that, in the cases which recover and subsequently present signs of motor disturbance, a similar, though less intense, lesion has existed."

In the last few years investigations into the causes of stillbirth have been carried out by numerous workers. In 167 cases examined Holland<sup>5</sup> found tears of the tentorium in 81 (48 per cent.), and all of these except 6 were accompanied by subdural haemorrhage. There is general agreement that meningeal haemorrhage is by far the most common cause of death in fresh non-macerated foetuses and in infants dying shortly after the conclusion of labour. It is impossible not to conclude, with Osler, that many, and perhaps the larger number, escape with their lives, but suffer permanent damage in varying degree.

There are, however, difficulties in the way of unqualified acceptance of the view that in the numerous cases of cerebral diplegia which present themselves later in life we are encountering the aftermath of this damage at the moment of birth. The interval between the birth and the time when the crippled child is first brought for advice is often long, and it is not always possible to rely upon the mother's memory of the details of labour, if, indeed, these have ever been told her. Moreover, when after this long interval opportunity presents itself for making a *post-mortem* examination, the scarred and atrophied brain shows no evidence of the nature of the original lesion which occurred so long ago, and which has been so long extinct.

Apart from the other views have been held of the dating from birth. There are those of cases as due to infective meningo-encephalitis, intra-natal or neo-natal. Virchow<sup>6</sup> speaks of "encephalitis interstitialis congenita," Henoch<sup>7</sup> of "haemorrhagic encephalitis." If we accept this view we must conclude that in general the infants recover, since routine investigations upon infants dying soon after birth show little evidence of encephalitis, but abundant evidence of haemorrhage. Cases which have come under our own notice suggest that trauma and haemorrhage themselves predispose to encephalitis. Probably the organization of the clot is always accompanied by a varying inflammatory reaction. The following is a good example of suppuration supervening upon haemorrhage. In this case there could be no doubt about the existence of the haemorrhage, because in addition to meningeal exudation there was a large clot within the substance of the brain.

An infant born at full time, in St. James's Hospital, Balham, with a breech presentation, after a difficult labour, was to some extent asphyxiated. Seen on the sixth day of life the fontanelle was tense and bulging, the pupils were unequal, and the limbs stiff and rigid. There had been repeated convulsions. On the sixth day the temperature rose to 104° F., and continued high. Death took place on the tenth day. At the autopsy the surface of the brain showed extensive suppurative meningitis as well as effusion of blood under the pia mater. In addition section of the brain showed a very large blood clot occupying a great part of the left hemisphere.

To assess the part played by developmental defect in the production of cerebral paraplegia or diplegia is even more difficult. Collier,<sup>8</sup> in an important paper, which has clearly influenced much subsequent writing on the subject, is inclined to deny etiological significance to meningeal haemorrhage occurring at birth, and, basing his opinion upon *post-mortem* studies, to lay greater stress upon faults of development. Space will not permit a full discussion of this difficult question. We believe that in general it is true to say that in cases of diplegia due to developmental defect we find that the

whole personality of the child is upon a low plane, that there is little power of auto-education, and that physical defects are constantly associated with the mental defect. The purpose of this paper is to lay stress upon the high degree of mental development which many of these children damaged at birth ultimately achieve, however great the delay in acquiring certain functions may be in infancy and early childhood. The great improvement shown by many cases of birth injury after the first few years of life appears to us to be due, not to the completion of a developmental process which has been subject to a mere delay, but to the final success of a process of self-education which has been achieved by the child's persistence in overcoming difficulties much greater than fall to the lot of the normal infant.

To illustrate the type of case we have in mind the following three histories may be quoted.

*Case 1.*—A boy of 15, long thought to be grossly mentally defective, though his mother refused to believe it, with spastic gait, stiff and clumsy hands, exaggerated mouthing speech, a vacant expressionless face, and a loud meaningless laugh, has nevertheless two intimate and devoted friends of his own age. He is a great collector of stamps and something of an authority on them. These two friends of his have pushed their way beyond all this unpromising exterior and have found behind it something to repay them.

*Case 2.*—A girl of 17, who was brought to one of us first at the age of 7, did not walk or speak until she was 4, and was thought to be an idiot. She now speaks fluently though a little monotonously. She walks well on the level but has difficulties with staircases. She writes laboriously, her whole body stiffened with the effort to control the pen. Yet her imaginative powers are so good that she was the author of a little play performed by the girls at her school.

*Case 3.*—A boy born very prematurely walked with great difficulty and with many falls in his third year. At 4 years old he could only articulate ten words, but from the age of 3 he had fallen into the way of expressing his wants by singing. Thus when he wanted his toy soldiers he hummed clearly and distinctly and in perfect tune the air of the hymn "Onward, Christian soldiers." During all this time the parents were well aware that visitors regarded him as mentally defective. At 6 he began to be able to articulate more clearly and to speak fairly well. It was then discovered how retentive was his memory with regard to what his mother had read to him before he could speak. Asked to name the twelve Apostles he confessed himself beaten, but said, "I can see them walking in the desert. Some of them are in front, some of them are behind, and the one that takes the money is in a *taxi*." He often refers to this or that as happening "before I could speak." Now at the age of 9 he is still inefficient at certain movements which require control. His handwriting is very bad, and he feeds himself untidily and with difficulty. Yet he does well at school, is far beyond the average in mathematical ability, and has very good general knowledge. He loves games, but is very bad at them.

No one now thinks these children idiotic and imbecile—no one, at least, who judges by more than a glance at the exterior. Yet in early childhood so great was the delay in the education of the sensorimotor paths that such was the opinion in each case. Not all cases, of course, achieve so much, but all show great initial delay and a surprising degree of subsequent improvement.

#### *The Latency of Symptoms during Early Infancy.*

With the symptoms which result from the meningeal haemorrhage at the moment of birth we are not at present concerned. Though as a rule sufficiently definite, in the absence of expert examination they may pass unnoticed or their significance may not be appreciated. After recovery from the initial shock of the haemorrhage it is clear that, as a rule, a period of latency follows which lasts for many months. A consideration of the order in which the different parts of the brain are developed explains the length of the interval which usually intervenes between birth, when the damage is sustained, and the time when the child is brought to the doctor and complaint is made of failure to grasp, to sit, to walk, or to speak.

Physiologically the brain of the newborn is active only in part. Its small size and weight (380 grams) is due to the fact that it is composed almost entirely of grey matter. While the cellular elements are complete and are not to be added to during the whole of life, the myelin sheaths which surround the nerve processes of the cells and which give the white appearance to the subcortical layer of the adult brain are developed only in very small part. Only those fibres are myelinated which are of immediate and vital importance to the newly born, those which preside over the functions of respiration, circulation, and nutrition, and those which have to do with certain reflex movements such as kicking, or automatic movements such as sucking. On the other hand, the fibres from the frontal, temporal, and occipital lobes, the commissural fibres (connecting the two halves of

the cerebrum) and the projection fibres (connecting the cortex with the lower parts of the central nervous system) are not myelinated until a varying time after birth, and are therefore, so far as we know, incapable of carrying impulses either afferent or efferent. The paths, in other words, which render possible complicated and controlled motor action and equipoise of the body are not developed.

In the normal infant, therefore, at birth and for some time thereafter, the nervous mechanism at work is almost entirely that of the medulla and spinal cord. All movements are reflex in character because the psychomotor centres in the brain are not developed. It follows from this that in early infancy symptoms will result only from lesions which at the time of birth affected the medulla and lower centres, and that the permanent ill effects of lesions which at the time of birth affected the cerebral cortex will appear later. In early infancy the cortical areas, in this sense, may be said to be "a silent area" of the brain.

The medulla, on the contrary, is active from the first, and it is interesting to note that in our series, in every instance in which we were able to recognize diplegia in an infant before the end of the third month, there were present symptoms of damage to the medulla, and that it was for these symptoms that advice was sought. In two cases the chief symptom noted was dysphagia and clumsiness in sucking; in two aphonia; in two stertor, apparently from palatal paresis. One of these last was about to be admitted to the diphtheria ward. In another older child, in whom the stertor had persisted, an operation for removal of adenoids had been undertaken without producing any change. The first case described by MacNutt showed this symptom, which made her "start forward" with the thought of tracheotomy in her mind. The subsequent history of these cases showed that all suffered more or less severely from diplegia. The immediate mortality of cases with subtentorial haemorrhage and medullary injury is probably very high, and explains the rarity with which they are met.

#### *The Ultimate Effect upon the Child's Physical Condition of Meningeal Haemorrhage at Birth.*

At birth and for some little time afterwards movement is governed altogether by the older and basic cord innervation. The assumption of cortical control is gradual and can be traced throughout the first year of life. In infants with damage due to meningeal haemorrhage the supremacy of the cortex is delayed or incomplete, so that movements and reflexes characteristic of earliest infancy persist for many years or are permanent.

In mammals experimental ablation of the cortex is said to produce the following results—results which are fleeting and transitory in animals lower in the scale of development, but which are in some degree permanent in the higher apes, although the passage of time brings about very great improvement.

1. A state of rigidity or tonic contraction due to the removal of the inhibitory influences of the higher centres which normally moderate and control the reflexes which determine the muscular tone.

2. An interference with "reciprocal innervation"—that is to say, with the simultaneous relaxation of antagonistic muscles which must accompany voluntary muscular contraction if it is to be effective and precise.

3. A loss of motor power and an imperfect capacity for apprehending the position and form of objects by means of the muscular and cutaneous senses—that is, a psychical paralysis of sensibility and motion.

Such a description applies with equal truth to the state of the normal infant at birth, because of the non-development of the necessary myelin sheath of the nerve processes, and in the varying degree to older children whose cortex has been damaged at birth. The muscles of these unfortunates are not powerless. They do not atrophy. They may even, when growth and nutrition is good, hypertrophy. Their failure to grasp, to walk, to speak, is due not to paresis of muscle, but to a disordered innervation which produces simultaneous contraction of antagonistic muscles. With the failure of the cortical control to develop efficiently, the muscular response to the voluntary impulse, though it may be powerful and in very widely disseminated, is ill regulated and ineffective. In some cases, on any attempt at performing a voluntary action the unduly diffused nervous impulse provokes a spasm which involves almost all the muscles in the body, gripping the limbs in rigid tones by the simultaneous contraction of antagonistic muscles.

The area of cortical damage or destruction determines the localization of the muscular defect. In many cases the damage is strictly confined to the uppermost parts of the Rolandic area, where lie the areas for the control of movements of the lower limbs. When the oozing of blood has been more extensive the damage may extend to the arm areas on either side, or finally to the areas for face, lips, and tongue. Although it is the rule rather than the exception to find the damage greater on one side than on the other, and paralysis is therefore present in unequal degree on the two sides, it is quite exceptional to find that one side has completely escaped and that hemiplegia has resulted. In true hemiplegia at birth it is probable that the lesion is within and not upon the surface of the brain. In the mildest cases paraplegia results, and in general cases of diplegia and cases of diplegia combined with pseudo-bulbar paralysis are due to more extensive and more severe injury. To this there are, however, exceptions. In not all the cases is the vertex cerebri the part to feel most severely the effect of the injury. Occasionally we meet with children whose arms are more affected than their legs, and with children in whom marked pseudo-bulbar symptoms are present with minimal symptoms of diplegia. Occasionally we find instead of spasm and hypertonus a very marked amyotonia, although the behaviour of the muscles upon attempted movement and the attitudes and involuntary movements which result are in other respects identical. It is possible that in these cases we have to deal with the results of subtentorial haemorrhage and a similar damage to the cerebellum. With cerebellar damage atonia, asthenia, and ataxia may be added to the picture.

Whatever the extent or distribution of the damage to the limb areas, when the child's body is at rest, nothing abnormal may be noticed. It is only the attempt to perform a voluntary movement which provokes the abnormal postures and spasm. Thus in cases of paraplegia the incapacity is often not apparent until the child is held in the upright position by the shoulders with feet hanging down to touch the ground. Then upon the attempt to walk or stand the legs become rigidly extended and adducted, so that the feet tend to cross in the so-called scissor gait, while the over-extension of the ankle brings the heels off the ground. It is not surprising that a child so affected may not achieve the power of standing for many years, when we consider how greatly the adductor spasm curtails the base upon which the body must be balanced. It is literally as difficult for such a child to walk as for a normal child to balance itself upon a tightrope. Similarly, on attempting to grasp, the child with diplegia finds the arms tend to become extended and adducted, the hands pronated, and the fingers separated and overextended. Once an object is grasped it can often be held firmly, though there may be difficulty again in relaxing the grip. The degree of spasm is very variable, but whether the limbs are held rigid or remain comparatively flexible to passive movement, the postures assumed on attempting voluntary movement are constant.

When the areas for the face, lips, and tongue have been damaged the expressionless face is very characteristic. The constantly changing facial play of the normal child is absent. The paresis is most marked about the lips, which are loose, prominent, and immobile. They are generally unable to retain the saliva, and when the child is held upright, so that saliva no longer gravitates to the back of the mouth, there is apt to be a great deal of dribbling. The reflex movements of sucking and the movements involved in chewing and swallowing are generally carried out sufficiently well to meet all requirements, although close observation of them will often show some slight loss of efficiency. Aerophagy is a common trouble. In a few cases the passage to solid food is only accomplished with great difficulty and after a long time. Speech is always greatly delayed. The complicated muscular movements involved are only learned slowly and with great difficulty. In the end the movements involved are exaggerated and the speech is monotonous and explosive. Dentals and labials present the greatest difficulties. The cry is expressionless and monotonous. It lacks the varying emotional tones which the normal child imparts to it. The laugh similarly is harsh and has no feeling in it. It is not, therefore, surprising that those who do not know the children well, who have no opportunity of recognizing the intelligence which lies hid behind the stiff face, and who judge by the immobile expression, the unsmooth attempts at speech, the vacant laugh and unmeaning cry, are apt to consider the children as obviously imbecile or idiotic.

In the group of cases which we have studied and which we regard as examples of the late effects of meningeal haemorrhage occurring during labour, the Wassermann test was always negative, the optic discs were normal except in one case with extensive choroiditis, and developmental abnormalities in other parts of the body were absent. Apart from the microcephaly of slight degree which was present in some of the worst cases, the children, though often small and slim, were in no way deformed or misshapen. The bird-like face and narrow frontal region of true microcephaly were never found. The ears were not misshapen, there was no tendency to obesity. Especially when seen asleep, when the want of facial expression is not apparent, and when the awkward limbs are at rest, the impression conveyed to the eye may be that of health and even of beauty. In many of the cases a disfiguring strabismus develops at some time during early childhood. In infants it appears less common.

#### *The Ultimate Effect upon the Child's Mental Development of Meningeal Haemorrhage Occurring at Birth.*

The intellect even of an idiot is in continuous evolution, and the worst cases respond to patient and persistent education by showing improvement. The results achieved by education depend, however, upon the cause of the mental defect. In general least success will be achieved in cases, with or without spasticity, in which there is numerical deficiency, irregular arrangement, and imperfect development of cortical neurons. The greatest success, on the other hand, will follow when the delay in mental development is due to sense deprivation, as in the striking cases of children who are both blind and deaf and who have achieved a high degree of mental culture elaborated from cognitions derived entirely from sensations of touch. In this sense the children whom we are now considering occupy an intermediate position. It is true that the cortical cells have been damaged,\* yet it would appear that, as a rule, though not perhaps always, the damage is sustained by one part of the cortex only—that which is concerned with the reception of tactile and muscular sensations and with the initiation of voluntary movements—and it is in these respects only that the children are defective. By every avenue which was closed to Helen Keller or to Laura Bridgman, both of whom from a very early age were blind and deaf, impulses freely reach the brain of these children. In due course the majority of them develop a high degree both of visual memory and of auditory word memory. But the one path by which Helen Keller and Laura Bridgman achieved so much is closed to them, or at least gravely obstructed.

It is by the sensations of touch and by muscle sense that the majority of impulses reach the brain during infancy. The baby carries every object to his mouth, that he may subject it to examination by lips and tongue, because they are most plentifully endowed with sensory nerve endings. As the cortex awakens to these repeated stimuli and develops under their influence the powers of the infant grow apace. Gradually the differential perception of stimuli becomes sufficiently advanced to enable the child to recognize the position of its body and limbs and to adjust them at will. It is the failure of the infant with diplegia to develop the power to sit or to grasp that usually first excites apprehension. The gradual change from the stiff spastic movements of the newborn to the freer play and more controlled action of the normal child at the sixth month is too subtle for its absence to be noted. But every mother knows that her baby should sit up before it is much older than six months. Thereafter the normal infant, able at will to adjust its body to space, developing a greater and greater mobility, accumulates knowledge at an ever-increasing rate by refining more and more its tactile, stereognostic, and muscular senses. The diplegic infant, relatively immobilized and anaesthetic, lags far behind. Few stimuli reach the brain, and therefore few elements capable of being utilized for new and more complex mental processes. For long the brain lies fallow. Hence it comes about, as we have almost always noticed, that during the second and perhaps the third years of life the mothers of these children have been intensely depressed by the visible

\* It is possible that haemorrhage spreading over the frontal lobes may lead to a greater degree of mental defect, but we have no example of this in our series. We have, however, met with at least one case in which diplegia appears to be combined with an aurosis. It is possible that this is due to involvement of the occipital lobes. The child is under observation, and it may be possible to decide the point later. This child is backward and foolish in behaviour, but at the age of 4 can sing the air of the "Marseillaise" with spirit.

want of progress. On all sides they are assured that the child is grossly mentally defective. It is only their perception that the visual and auditory memory of the child is relatively unimpaired that accounts for their steadfast refusal to believe it. Except in a few of the worst cases with microcephaly, and especially when there have been repeated convulsions, the mothers of these children have throughout maintained that the intelligence is good, and that, although they cannot speak, they understand every word that is said and that their memory is good.

In another way also the diplegic is apt to contrast with the child who is mentally defective. In spastic idiots the attention is weak, and cannot be fixed on anything. They touch many objects one after the other, but show none of that curiosity which is truly attentive. Their actions are inconclusive; they show no joy in the exercise of their powers or patience in practising them. It is striking to watch how differently in these respects the child who suffered from injury at birth may act. More and more he works with us in the attempt to overcome his disability. Though he cannot walk, if he is held upright he works his stiff little limbs with a will, laughing aloud with delight. Little by little, with infinite pains, he learns to grasp, to balance, to walk, and when, years later, he too achieves a degree of mobility and control the improvement is striking. It is just this power of auto-education which is conspicuously lacking in the imbecile or the idiot. In later childhood the progress is often so rapid that the mother, previously so despondent, eagerly expresses her satisfaction, while she is now able to convince others easily enough that the mental powers of the child are considerable.

It is in general only when the sensory and motor loss extends to and involves the hands that the confusion with primary mental defect arises. Those who are only paraplegic walk late and with difficulty, but are not thought to be idiots. They may be excitable and restless, because their helplessness leaves them too long in their mothers' arms, without sufficient outlet for their energies, but of their cleverness there is often no doubt whatever.

But when the hands, all-important as they are for the auto-education of the infant, are insensitive and parietic, for the time being contact with environment is almost completely lost. Head has emphasized how extensive is the area of cortex which is devoted to the reception of sensations derived from the opposing surfaces of thumb and index finger. To the precision and complexity of the movements of the human hand, slowly acquired by the race in the course of ages, man owes his preservation and supremacy. And in the early months and years of life the infant, in its striving and progress, must recapitulate the story of its race. If it cannot, if the development of the hand is retarded, the avenue to the brain along which in normal infancy almost all the traffic passes is narrowed and obstructed. When there is added injury to the voluntary centres which control lips and tongue so that speech too is absent, the difficulties are still further increased. For speech is not only a means of expressing thought: speech clarifies thinking.

A long and close study of a group of some thirty of these cases--of all ages from earliest infancy to adolescence--has convinced us that they differ unmistakably from cases of primary mental defect with spasticity due to developmental causes. In a few frequent and persistent epileptiform convulsions have played havoc with the intelligence. After each convulsion the consequent deterioration in energy and achievement may be appreciable. But if convulsions are not present the defect commonly remains limited to a loss of voluntary movement and of sensation, involving a greater or a less extent of the body. The resulting retardation in development is most apparent in the first years of life, because

\* It is very probable that Lord Byron's lameness was due to paraplegia as a result of a birth injury. Whatever its nature, it is clear at least that it was not due to a "club-foot." The lasts on which his boots were made are piously preserved in the Nottingham Museum, and they are symmetrical and well shaped. Mr. John Murray, of Albemarle Street, has been good enough to show me two surgical boots made for Byron as a boy. They show a long and slender foot. By a contemporary writer the poet is described as entering a room with a curious running movement, "running rather than walking." Again, "He moved with a peculiar sliding gait." In fact, with the gait of a person walking on the balls and toes of his feet. It is clear that the disability was much greater in early childhood, and was overcome to a considerable extent as he grew older. As a child he was taken to John Hunter, to Dr. Baillie, and many other doctors. Later he played cricket for Harrow, though with someone to run for him, and as well endowed: personal beauty, false modesty at his birth. He suffered from repeated epileptiform convulsions.

education at that age proceeds by the refinement and analysis of sensation. The auditory and visual paths then are relatively unimportant. Gradually, by constant effort and with a success which varies with the extent of the original lesion, the child achieves in whole or in part that control of movement which comes so easily to the normal infant. From an early stage, however, those who know the children well can appreciate that despite the spastic limbs, the immobile face, or incoherent speech, the intelligence of the child is alert. Observation, memory, concentration of purpose, affection, intuition, and reasoning may be on a comparatively high level. No doubt the children are apt to be nervous and unstable. Like some caged animal, cut off from the stimulus of environment, they are apt to show strange traits--to have a capricious or unnatural appetite, to sleep badly, or to be unduly timid. These are drawbacks often perhaps inevitable, but with sheer mental defect they have nothing to do. In general it may be said that the response shown by these children to suitable education is remarkable. For them the methods elaborated by Dr. Montessori are especially applicable, and may give the happiest results. In later childhood, even when the voluntary movements remain very inco-ordinate, the mental powers may finally attain a very considerable development.

#### Conclusions.

1. Among cases of infantile diplegia or paraplegia it is possible to recognize a group in which the defect is confined to the sensorimotor cortical areas.
2. Probably all cases in this group are due to birth injury, although all cases of birth injury may not belong to the group.
3. Since education at first proceeds almost entirely by sensorimotor paths there is in early childhood a deceptive appearance of gross mental defect.
4. In later childhood progress may be rapid and recovery almost complete. The difficulty is overcome by the remarkable persistence in effort which is characteristic of most of these children. Even when voluntary movements remain stiff and awkward the child may be a quick learner by eye and ear. Inco-ordination may remain though character and intelligence may be on a high plane.

## THE MODIFICATION OF GASTRIC FUNCTION BY MEANS OF DRUGS.\*

BY

T. IZOD BENNETT, M.D.,

ASSISTANT PHYSICIAN, MIDDLESEX HOSPITAL; ASSISTANT TO THE  
PROFESSOR OF PHYSIOLOGY, MIDDLESEX HOSPITAL; REIT  
MEMORIAL FELLOW FOR MEDICAL RESEARCH.

(From the Department of Physiology, Middlesex Hospital.)

EVERYONE engaged in the practice of medicine is aware of the gulf separating the beliefs of the physician actively occupied in treating diseases and their symptoms, from the knowledge, precise but meagre, of the experimental pharmacologist. Whereas human hope and optimism have during many ages collected a series of remedies, often of unknown or varying composition, which may do good, the critical scientist, meticulously rejecting everything incapable of objective proof, has been unable to point to more than a very few substances which have definite organic actions, and has been obliged to condemn, as apparently inactive, large numbers of those agents which had previously been held to be of curative value.

In no branch of medicine is this contrast more apparent than in that which deals with disorders of the stomach; for medical writers, from the earliest times, have given enormous lists of remedies for such conditions, but it is with difficulty that the student can find, in any modern textbook of pharmacology, reference to drugs which can in any way modify gastric function. There has, indeed, until recent

\* A paper read before the Section of Therapeutics and Pharmacology, Royal Society of Medicine, October, 1922. The expenses incurred in connection with the researchs have been partially defrayed by a Government grant made through the Royal Society.

years been so little experimental work carried on in connexion with the stomach that the reticence of the pharmacologists is natural, and the growth of knowledge in physiology has made clear so many errors in the reasoning of earlier writers that the discrepancy between traditional belief and proven facts is to a large extent explained. In this paper it is my endeavour to collect some recent experimental work concerning substances which can be demonstrated to affect gastric function; they can, I think, be best classified into (1) those whose chief action is on gastric secretion, and (2) those whose action is rather on gastric motility.

#### SUBSTANCES AFFECTING GASTRIC SECRETION.

##### 1. Diminishing Gastric Secretion: Atropine.

For producing this effect we have an effective drug—namely, atropine. Very conflicting accounts have been published as to its gastric effects; thus Crohn<sup>1</sup> reports failure to produce any diminution in gastric acidity, whilst Bastedo<sup>2</sup> states that the atropine completely fails to affect hyperacidity and only checks acidity in hypersecretory cases in the period after the digestive stage is over. Other observers, notably Chiari,<sup>3</sup> Mathieu,<sup>4</sup> Schmidt,<sup>5</sup> and Bergmann,<sup>6</sup> speak highly of the inhibitory effects of this drug, and my own observations are in complete accord with this belief.

In Fig. 1 is seen the curve of free HCl obtained on fractional gastric analysis of a subject with a very free secretion of acid; the second curve shows the modification produced in this curve by the hypodermic injection of 1/100 grain of atropine sulphate. The effect is definite, and it must be observed that the curve being obtained from analysis of gastric contents, it could not be expected that the atropine would affect the HCl which had already been poured into the stomach before the drug was administered.

But it is by oral administration of atropine or belladonna that the most marked effects can be produced. If the empty stomach be washed with a very weak solution of atropine even for a few moments, the fluid being then withdrawn, a marked inhibition of secretion is produced. Fig. 2 illustrates such a case, the heavy line being the subject's normal curve of gastric HCl, the broken line the curve subsequent to such a washing.

This is an experiment which I have many times repeated; it has been confirmed by Roberts,<sup>7</sup> and it can be said that this local effect of atropine on the gastric mucosa is as definite as is the effect of the same drug when applied to the conjunctiva. It is probably because observers have chosen the hypodermic route that discordant results have been obtained.

Since performing these experiments it has become my custom in practice, when I desire to reduce gastric secretion, to administer atropine in small doses and in a large volume of water, the whole being given on an empty stomach.

##### 2. Increasing Gastric Secretion.

For this purpose pilocarpine has somewhat naturally been recommended, and with certain precautions an increase can

actually be obtained. By washing the stomach with weak solutions I have sometimes succeeded in raising the curve of gastric HCl, as in Fig. 3, but usually, even when very small doses are applied, a local wash is absorbed, for the subject soon observes profuse salivation, and this saliva, if swallowed, will have a diluting effect on the stomach contents sufficient to reduce the acidity below its normal figure.

##### 3. Substances Affecting the Gastric Secretion after its Evolution.

###### (a) Substances Neutralizing Acid Secretion.

In this group must be placed all the alkaline salts which have so long been used for the treatment of true or supposedly pathological excesses of gastric hydrochloric acid.

Following Pavlov, Bickel, Rosenblatt, and a score of others declared that such alkalis not only neutralized, but actually

arrested the secretion of HCl by the stomach. Du Mesnil, Bourget, von Leube, and others were, however, of opinion that the alkalis, and particularly sodium bicarbonate, were actual stimulants to gastric secretion, a belief which had the support of Claude Bernard<sup>8</sup> himself. The fractional method of gastric analysis has enabled us to procure more

definite evidence on this controversy than previously existed, and it has now been clearly shown that the effects of alkali administration are very much influenced by the time of administration.

In Fig. 4, for example, will be seen the normal curve of a healthy subject, and the curve from the same subject as influenced by giving sodium bicarbonate prior to a meal; it will be seen that during the period following the meal the alkali, rapidly neutralized, has led to an actual increase in the acid secretion.

In Fig. 5, on the other hand, is seen the effect of the administration of alkali at a later period; the acid already secreted is fully neutralized and a period of neutrality

lasting nearly an hour is followed by a rapid rise in the gastric acidity to its usual level. Magnesium hydroxide 12 grains and sodium citrate 5 grains were employed in this experiment.

In all such experiments it must be borne in mind that the gastric contents are not homogeneous, but the fractional method carefully

employed does give samples which offer a reasonable idea of the reaction of the total stomach content. In general, from the experiments of Crohn<sup>1</sup> and from my own observations, I feel that it may be said:

1. That sodium bicarbonate tends to excite the gastric mucosa to increased secretion, and that this effect more than counterbalances the neutralizing effect of the salt.
2. That other salts, particularly magnesium oxide, and bismuth oxy-carbonate, have far less stimulating effect, and the former, weight for weight, possesses greater neutralizing power.
3. That the rational method of employment of these salts in cases of hyperacidity is to administer them at such periods after meals as will lead to their neutralizing

FIG. 1.—Showing effect on gastric secretion produced by hypodermic administration of atropine. Heavy line = subject's usual curve of HCl (fractional gastric analysis). Broken line = same after hypodermic injection of 1/100 grain atropine sulphate at point marked by arrow.

FIG. 2.—Showing effect on gastric secretion produced by washing the stomach with weak solution of atropine. Heavy line = subject's usual curve of HCl (fractional gastric analysis). Broken line = curve after preliminary wash with very weak solution of atropine.

FIG. 3.—Showing effect on gastric secretion produced by washing the stomach with weak solution of pilocarpine. Heavy line = subject's usual curve of HCl (fractional gastric analysis). Broken line = curve after preliminary wash with weak solution of pilocarpine. Lowest line = more usual result, due to dilution of gastric content by saliva.

FIG. 4.—Showing increase in secretion of HCl produced by oral administration of sodium bicarbonate before meals. Heavy line = subject's normal curve. Broken line = curve when 120 grains of sodium bicarbonate had been given a quarter of an hour before meal.

effect coming into play without there being the possibility of producing any marked effect on the actual gastric cells.

4. That for producing inhibition of secretion reliance must be placed on drugs such as atropine and its derivatives.

5. That in gastric therapy sodium bicarbonate finds its greatest usefulness in those rather rare cases in which there is an excess of mucous secretion with low or absent hydrochloric acid.

FIG. 5.—Showing neutralizing effect of magnesium oxide given after meal. The broken line shows complete neutralization, lasting three-quarters of an hour, produced by giving 12 g. of magnesium oxide.

#### (b) Substances Replacing Deficient Acid Secretion: Hydrochloric Acid.

In cases where the gastric secretion of HCl is deficient or absent it has long been customary to give HCl by mouth; the practice is justified both on logical grounds and by the results obtained, but it is of interest to consider what the mechanism may be by which the result is obtained. In the first place it must be recognized that in order to obtain a concentration of HCl anywhere near that seen in the normal subject very large amounts of the acid must be administered to patients with achlorhydria. Thus, if the volume of a meal be reckoned approximately to be about one pint, it is necessary to give nearly two drachms of the B.P. dilute acid in order to raise the concentration of that amount of water to 0.1 per cent. HCl, and as all normal meals contain protein, which readily absorbs HCl, a great deal more than that quantity must be given if a serious effort is being made to increase the acidity of the gastric contents.

These considerations apply to cases of achylia gastrica, for it is doubtful whether the administration of HCl to cases of mere hypochlorhydria has any effect at all. Boldyreff,<sup>9</sup> and more recently Rehfuss,<sup>10</sup> have shown that in normal subjects any artificial increase in the HCl of the stomach contents is followed by a compensatory regurgitation of alkali from the duodenum, which quickly restores the acidity to its normal level.

It is, then, difficult to believe that the small doses of HCl usually given in cases of achlorhydria can have any but a psychic effect; but given more rationally there can be no doubt that striking results are often obtained, particularly in cases of achylia with diarrhoea. An interesting case was recently reported<sup>11</sup> in which a doctor with severe chronic diarrhoea and anaemia was apparently cured by such means; in this case the physician administered as much as half a litre of 0.5 per cent. HCl to the patient daily, introducing the acid by means of a gastric tube. One is unable to accept this case as a proven one of Addison's anaemia—the blood picture was not conclusive; but that a striking cure of an almost desperate case was secured is beyond dispute. My experience with HCl in pernicious anaemia is less encouraging; I have often produced temporary improvement in the intestinal symptoms, but never obtained evidence of anything suggesting cure. In a recent case—a particularly severe one with little sign of regeneration—I gave as much as half a pint of 0.5 per cent. HCl daily to the patient without apparently arresting the disease in any way. It should be added that this case had no diarrhoea, and further that no trouble was experienced in giving the acid by mouth, it being sucked through a tube in order to protect the teeth.

When one comes to inquire critically as to the true effects of the HCl secreted by the stomach, one is obliged to say that in general its functions are not essential to the organism. Thus its hydrolytic effects on protein can be replaced by the action of enzymes in the small intestine; its effect on the closure of the pyloric sphincter, if definite, is not the only means of closing that valve; again, even if HCl does normally bring about pancreatic secretion on its entrance into the duodenum, it is certain that achlorhydric subjects have usually a perfectly normal secretion of pancreatic juice.

Two effects predominate, the first being that on pyloric closure. There is no doubt but that such cases of achylia gastrica, and especially those with pernicious anaemia, have rapidly emptying stomachs, and the addition of HCl slows down this process. The second great function of HCl would appear to be its antiseptic action, and here again its oral administration in cases of achylia is, I believe, fully justified. I have here a flask which contains fluid removed from the fasting stomach of a patient with duodenal ulcer; the concentration of HCl in this case was very great, being that of decinormal acid. You will observe that though this juice has now stood exposed to the air for six months it is quite odourless, and no microbial growth has occurred in it. Similar samples from achlorhydric cases are foul-smelling in the course of a day or two.

#### A NOTE ON THE BITTERS.

This section would be incomplete without reference to the bitters, a series of preparations which have long enjoyed high repute in gastric medication. Textbooks have at times attributed to the bitters an effect in stimulating gastric secretion; later they have been said merely to increase appetite, and still more recently it has been said that their effect is actually nil.

The most complete recent study is by Carlson<sup>12</sup>; he showed that in the fasting state the bitters have no effect upon the hunger contractions of the stomach, and further that no definite influence on gastric secretion could be demonstrated. His observations were largely obtained from a human subject in whom complete stenosis of the oesophagus had been relieved by the establishment of a permanent gastrostomy. This young man, who was otherwise in perfect health, made it his custom to chew up his food in the normal way, and then to inject it into his stomach by means of a syringe. Carlson made observations on the amount and quality of the juice which could readily be extracted from this subject's stomach, and in a series of experiments with bitters he measured the juice after the mouth had been washed out with gentian, quassia, columba, and other drugs. He was unable to obtain any evidence of an increase in gastric secretion, nor did this subject observe any increase in appetite.

Carlson made a further series of observations on patients with loss of appetite; it was found that though the patients often said that their appetite had been improved by these medicines, measurement of their food consumption showed an increase of little more than 2 oz. in the amount eaten at each meal.

Making observations on the gastric secretion by means of the modified Einhorn tube, I have never been able to secure any definite increase in secretion by giving the subjects bitters as a preliminary mouth-wash; in several cases there has been an apparent decrease in HCl secretion, an effect which I believe is due to the somewhat profuse salivation sometimes caused. As in the case of pilocarpine, such saliva, if swallowed, will tend to dilute the gastric contents, and so diminish acidity.

It must, then, be concluded that we have no evidence of any marked effect on gastric function produced by the bitters, but there should, I think, be added the rider that, in fatigued states, the alcohol in which the bitters of the commonly used *apéritifs* are dissolved often removes from the subject unpleasant fatigue symptoms which may be a serious factor in inhibiting appetite, and possibly digestion also. Put in cruder terms, it is probable that a whisky and soda, or the army rum ration, is as effective an aid to appetite and digestion as is the more conventional cocktail, or sherry and bitters, or the less attractive condurango or quassia water.

#### DRUGS AFFECTING GASTRIC MOTILITY.

##### 1. Atropine.

In the work to which I have already referred I found that in addition to its inhibitory action on secretion, there was evidence that atropine delayed gastric emptying. The effect was, however, not marked; whether by its hypodermic use or by its local application, the delay in emptying did not as a rule exceed a quarter of an hour with a test meal of the usual composition.

But it must be remembered that strong evidence exists showing that in cases of abnormal spasm of the gastric musculature the effect of atropine may be very marked. It has, indeed, become a matter of everyday radiographic practice to give large doses of this drug in order that the under-

lying cause of such spasms may be sought for. Thus it is no unusual thing for a patient with gastric ulcer to exhibit hour-glass constriction of the stomach on x-ray examination; if, however, he be re-examined after administration of full doses of atropine for three days, the constriction is seen to have disappeared, and the crater of an ulcer is often demonstrable. In cases of pylorospasm without discoverable organic lesion the patient's condition is sometimes remarkably improved by atropine treatment; one feels that such cases of disturbed gastric rhythm may to some degree be compared to those cases of auricular fibrillation with tachycardia which derive such striking benefit from the heart-block produced by the digitalis group.

### 2. *Pilocarpine.*

Fractional gastric analysis before and after lavage with pilocarpine demonstrates an increased rapidity of emptying after the use of this drug. The change is of a degree equivalent to the delay by atropine, and no really striking effect can be produced by doses which are within the limits of safety.

### 3. *Strychnine.*

This drug has long been given an important place in gastric therapeutics as a supposed means of increasing gastric motility.

An elaborate investigation recently published by an Italian observer, A. Berti,<sup>13</sup> enables us to examine the question to-day from a better informed standpoint.

In addition to a considerable number of experiments on cats, Berti carried out a large series of observations on human beings, more than fifty subjects being employed, some of them being healthy students, others patients with viscerophtosis. All were examined under strict experimental conditions. At 8 a.m. an euema was given to secure complete evacuation of the colon; at 9 a.m. a test meal consisting of milky gruel containing barium and bismuth salts was swallowed, and x-ray observations of the stomach were then made half-hourly until the organ was empty. Two such observations were made on each subject, one with the plain meal, the other after administration of strychnine, several weeks being allowed to intervene between the two observations.

The strychnine was given in varying doses, both by mouth and hypodermically, with results which may be summarized as follows:

#### *Nitrate of Strychnine given by Mouth.*

(a) *Half-milligram.*—At first peristaltic movements were increased both in rapidity and depth and there was a marked diminution in the size of the pyloric antrum, evacuation of the stomach began sooner, and continued more rapidly than normal. Observed an hour later the peristaltic movements had lost much of their intensity, but the net effect of the drug had been to accelerate gastric emptying by more than half an hour. (Fig. 6, A.)

(b) *One Milligram.*—Again there was marked initial increase in peristaltic movement, but after an hour the contraction of the pars pylorica was sufficient to delay emptying, and, the peristaltic waves having become very feeble, there was on the whole a delay in the complete emptying of the stomach.

(c) *Two Milligrams.*—With this dosage the initial gastric movements were precipitate, there being a marked hypertonus of the pyloric region, violent peristaltic waves coming along the greater curvature, two or three being simultaneously visible, the whole producing a marked increase in the volume evacuated from the stomach in the first half-hour. But after the first hour these movements became feeble and feeble, hypertonus persisted, and the net effect was that there was considerable delay in complete gastric emptying. (Fig. 6, B.)

(d) *Three and Four Milligrams.*—The above phenomena were further accentuated; at first violent peristaltic waves coursed along to the pyloric region, where they often became arrested, forming an appearance suggestive of a string of sausages, or even contracting this portion to such an extent that the cardiac end of the stomach alone was visible. And again there was a rapid tiring

of these waves so that final evacuation was retarded, the stomach a normal. (Figs. 6, C, and 7.) It is seen the final expression of emptying being followed by the production of an hour-glass appearance. The general hypertonus appeared to be so great as to prevent peristaltic movement, the final hour-glass appearance being due to an extreme persistent contraction similar to that often observed in cases of saddle-ulcer of the lesser curvature. (Fig. 6, D.)

#### *Hypodermic Administration.*

With this method of administration the above effects were produced with smaller doses, in general each hypodermic dose producing the effect of about double the quantity taken by mouth.

My own work with strychnine has been limited, but several observations which I have made tend to confirm these findings, and it must, I think, be concluded that to produce

any beneficial effect on gastric motility very small doses of strychnine must be employed. The effects of larger doses are of considerable interest in throwing light both on the physiology of the stomach and on the motor disturbances of chronic ulceration. They seem to demonstrate once more the essential difference which exists between the motor functions of the fundus and those

of the pyloric portion of the stomach, and they elucidate the phenomena by which spasmodic hour-glass constrictions are produced.

When speaking of the motor effects of atropine I drew attention to the power of this drug in controlling spasm; it would be an interesting experiment to see whether strychnine spasm of the stomach could be controlled in this way.

#### *A NOTE ON ADRENALINE.*

The use of this substance in gastric therapeutics is, as far as I am aware, confined to cases where it has been employed in the endeavour to check haemorrhage. It should, on theoretical grounds, be capable of affecting both gastric secretion and gastric motility if its action could be brought to bear on the sympathetic nerve fibres supplying the stomach.

In 1920 Venables and I<sup>14</sup> were able to demonstrate the very marked gastric effects which can be produced by unpleasant psychic influences—the suggestion of nausea or of fear being sufficient to delay gastric emptying for a considerable time and to inhibit the secretion of acid. It has been the custom of many physiologists to explain such effects as being the result of an increased outpouring of the internal secretion of the adrenals into the blood stream, with consequent effects on local tissues supplied with sympathetic fibres.

With such ideas in mind, I have carried out a series of experiments on normal men. On each subject two observations were made—in one the stomach was washed with water and a test meal given after, in the other the stomach was washed with adrenaline in various strengths and the test meal given as before. I have been able to obtain no evidence of any gastric effect of adrenaline by this means, though I have used strengths of as much as 1 in 5, and have used sufficient to ensure a washing of the greater part of the gastric mucosa.

In a second series of observations the substance was used hypodermically, water being used in the controls. Again I have failed to demonstrate any gastric effect, though various doses have been tried, and blood pressure and subjective effects have sometimes been demonstrable.

Whether the use of adrenaline in cases of haematemesis is wise is at present a matter of controversy; that it has any effect on gastric secretion or motility my present series of observations does not support.

It is probable that the future will produce much experi-

FIG. 6.—Showing the effect on gastric motility produced by strychnine. A, 0.5 milligram; B, 2 milligrams; C, 4 milligrams; D, 6 milligrams. (After Berti.)

FIG. 7.—Showing effect produced by administration of strychnine. A, 3 milligrams; B, 4 milligrams. (After Berti.)

mental work which will enable us to employ a greater variety of drugs with definite effects on gastric function; it has been my endeavour in this paper to show that we already have a limited series of such substances, and I feel that the selection of those with certain properties must lead to a steady improvement in the treatment of the disease.

I would in conclusion express my thanks to my colleagues and the students of the Middlesex Hospital, in whose physiological department all my recent experiments have been conducted, and on whose generous help I have always been dependent.

## THE TREATMENT OF KALA-AZAR BY "BAYER 205."

BY

WARRINGTON YORKE, M.D.,

PROFESSOR OF PARASITOLOGY, SCHOOL OF TROPICAL MEDICINE,  
UNIVERSITY OF LIVERPOOL.

THE following case, in which the drug "Bayer 205" was used with success in the treatment of kala-azar, is worthy of record, more especially as the only case hitherto reported ended disastrously.

A Jaccar, aged 22, left Bengal, in apparently good health, at the end of July, 1922. He became ill on August 12th, and in September noticed a swelling in the abdomen. He was treated with quinine on board ship and also at Cape Town, but did not improve and steadily lost weight. On November 8th he was sent to the Liverpool School of Tropical Medicine as a case of malaria with enlarged liver and spleen. He was emaciated (weight 93 lb.), the liver and spleen were considerably enlarged, the tendings well below the umbilicus to within 1 inch of the brim of the pelvis; the temperature to 100°. Examination of the blood for malaria parasites was negative. A leucocyte count revealed marked leucopenia—2,000 leucocytes per cubic millimetre. On careful searching of a whole blood film a single *Leishmania* was found. The faeces were normal and negative, except for the presence of a few *Ascaris* eggs. On November 13th the weight was 94 lb. A few *Leishmania* were again found in the blood on November 15th, and a spleen puncture made the following day revealed the presence of the parasites in very large numbers. The blood gave a well marked formal-gel reaction, and the urine contained a faint trace of albumin.

It was decided to treat the patient with tartar emetic administered by the rectum, and from November 16th to 20th daily injections of 1 grain in half an ounce of water were given; from November 21st to 23rd the daily dose was increased to 2½ grains of tartar emetic. The temperature, which, except for a couple of rises to 100° F., had been normal until November 19th, commenced to rise on this date and continued to oscillate between 100° and 101° F.; the weight on November 23rd was 93 lb. No injections were given from November 24th to 26th, but on November 27th injections of 2½ grains were resumed and continued to December 20th. The temperature remained above normal, rising at times as high as 102° F., until December 2nd, when it again became normal and has since remained so. The weight, however, gradually decreased until December 17th, when it was only 88 lb. On December 11th the leucocyte count had increased to 5,000 per cubic millimetre, but on December 12th a few *Leishmania* were found in the peripheral blood.

From November 16th to December 20th the patient had received by the rectum a total of 105 grains of tartar emetic; the injections, which were only half an ounce in volume, were well retained, and that some antimony at least was absorbed there is no doubt, as the urine examined on November 21st, and on subsequent occasions, was found to contain very definite quantities of the drug. From December 21st to 27th no treatment was given. A spleen puncture made on the latter date revealed the presence of *Leishmania* in considerable numbers, but so far as one could judge, not in such great numbers as on the occasion of the previous puncture on November 16th. On December 23rd the weight was 91 lb., an increase of 3 lb. during the week.

Whilst, therefore, there is some evidence that the intra-rectal course of tartar emetic had been beneficial to the patient, and had possibly to some extent reduced the mass of the infection, and perhaps might have resulted in still further benefit had it been continued, it is obvious that it

had by no means cured the disease. Under its influence the temperature had returned to normal, the general condition of the patient had improved, the leucocyte count had risen, and the parasites in the spleen had apparently become less numerous; but, on the other hand, the weight had continued to fall, the spleen and liver had not decreased in size, and parasites had disappeared neither from the peripheral blood nor from the spleen.

It was then determined to ascertain the effect of "Bayer 205" on this disease. The formula of the drug, which is a preparation of the German chemical firm Messrs. Friedr. Bayer and Co. of Elberfeld, has not yet been disclosed. It has recently been used with great success in the treatment of trypanosomiasis of man and stock. It has also been tried in various other diseases of man and stock—namely, in malaria, recurrent fever, and general paralysis of man, and in the pyroplasmoses of domestic animals—but without any success.

So far as I am aware, the only occasion on which the drug has been used in kala-azar is the case recently recorded by Mollow (1922). In this case only a very small dose (0.2 gram) was given, but the result was disastrous, the patient quickly developing alarming symptoms—severe rigors, headache, haemorrhages from nose and gums, severe vomiting which later became haemorrhagic, and collapse; later the patient became violently delirious, and finally death occurred sixteen hours after the injection. In view of this record the treatment of the present case by "Bayer 205" was undertaken with some little trepidation.

On December 23rd an intravenous injection of 0.25 gram of "Bayer 205" was given. This injection, which in Mollow's case had rapidly proved fatal, produced not the slightest effect in the present case; the temperature remained normal, and the patient complained of no unusual sensation. On December 30th the weight had increased to 93 lb., and a second intravenous injection of 0.5 gram of "Bayer 205" was given; this likewise was attended by no ill effect—the temperature remained unchanged, the patient complained of nothing, and the urine remained normal. On January 2nd it was noticed that the spleen had shrunk perceptibly, and a third injection of 1 gram of the drug was then given, and again no reaction was observed. On the following day the weight was 96 lb. On January 5th it was noticed that the spleen had further decreased considerably in size; a final injection of 1 gram of the drug was given on this date, and, as on the previous occasion, was unattended by any rise of temperature or other sign of reaction. By January 8th the spleen had shrunk at least two inches, and was well above the umbilicus. On January 13th the weight was 101 lb., and the spleen had shrunk still further; a trace of albumin was found in the urine. On January 20th a spleen puncture was made, but no parasites were found; the weight was 103 lb. On January 28th another spleen puncture was made, and this was also negative; the spleen had decreased in size to such a degree that it now extended only about 1½ inches below the costal margin, and a somewhat comparable though less obvious decrease in size of the liver was also noted; the formal-gel reaction was still positive, the urine no longer contained albumin, and the weight had increased to 105 lb. The patient sailed for India apparently in excellent health on January 30th.

The history of this case suggests that "Bayer 205" has a very definite and rapid action in kala-azar. The injection of the drug was followed by no ill effect; the spleen rapidly decreased in size, as did also the liver, though to a less obvious extent; the general condition of the patient improved, he rapidly gained in weight, putting on 14 lb. within a month, and two spleen punctures, made respectively fifteen days and twenty-three days after the last injection of the drug, were both negative.

Possibly the violent and rapidly fatal symptoms observed in Mollow's case after the administration of so small a dose of the drug as 0.2 gram are to be explained, as the author suggests, on the ground that the patient was in an extremely poor condition at the time of the injection.

I am indebted to Messrs. Friedr. Bayer and Co. for kindly supplying me with a quantity of "Bayer 205" for trial.

## REFERENCE.

Mollow, W. (1922): *Arch. f. Schiffs- u. Trop. Hyg.*, Bd. 25, H. 2.

A ROMAN Catholic Congress on the question of population will be held at Tilburg or Breda on April 12th and 13th, when the medical aspects of the question will be discussed by Professor Frans Daels of Ghent and Dr. A. W. Aussen of Utrecht.

DR. SOPHIE A. NORDHOFF-JUNG of Washington has founded an annual prize of 500 dollars, to bear her name, for the best work on the etiology, prophylaxis, and treatment of cancer. The judges will consist of members of the Munich Medical Faculty. The first award will be made at the end of this year.

## THE TREATMENT OF ANKYLOSTOMIASIS WITH BETA-NAPHTHOL AND THYMOL.

BY

HARRY G. PHIPPEN, M.R.C.S.ENG., L.R.C.P.LOND.,  
MEDICAL OFFICER, ZANZIBAR.

THE following notes on the treatment for ankylostomiasis which I have carried out for the past eighteen months in Zanzibar and Pemba, where the disease is very prevalent and known as "safuri" and "baridi," may be worth recording.

If the patients are debilitated and anaemic, as the majority are, before commencing the treatment proper I give them thrice, daily a tonic containing ferri et ammon. citr., liquor arsenicalis, and liquor ammon. fort., which is continued in the intervals of treatment, and also afterwards until the patient is quite strong.

If possible I have them in hospital for preparation and treatment, or if they are unable to stay in hospital I get them to come in for one day weekly for treatment, which is as follows: In the evening I give a powder containing calomel 5 grains and sodium bicarbonate 10 grains. This is followed at 7 o'clock next morning with a draught of sodium sulphate 3 drachms, in water to 3 ounces. At 8 a.m. I give a mixture containing beta-naphthol 1/2 drachm, thymol 1/2 drachm, mucilage q.s., and water to 1 ounce. At 10 a.m. I repeat the beta-naphthol and thymol mixture, and keep the patients in bed until about 4 p.m., not allowing them any food or liquid whatever; after that time they are allowed fluid diet only for the remainder of the day. Those desiring to leave hospital may do so, to report again in seven days for treatment; but they send a specimen of their faeces on the day after leaving hospital for microscopical examination for the ova of ankylostoma. This is done after each treatment until free.

Of 171 cases treated I have been able to follow out the results of 116, the remainder not having reported for further treatment. The results are as follows: After one treatment, 34.5 per cent. were cured; after two treatments, 25 per cent.; after three, 17 per cent.; after four, 13 per cent.; after five, 6 per cent.; after six, 7 per cent.; after seven, 4 per cent.; after eight, 1 per cent. I have not given the fractions of the percentage, but have taken it to the nearest figure. In no case did I give more than eight treatments.

It is interesting to note that in some cases other well known treatments had been previously tried without effect, as the following cases will show:

*Case 1.*—After ten treatments of thymol ova were still present; the case was negative after three treatments with beta-naphthol and thymol.

*Case 2.*—After thirty-two thymol and three oil of eucalyptus treatments ova were still present; the case was negative after three treatments with beta-naphthol and thymol.

*Case 3.*—After three treatments with oil of chenopodium ova were still present; the case was negative after one beta-naphthol and thymol treatment.

*Case 4.*—After prolonged antimony treatment the case was still positive, but became negative after one treatment with beta-naphthol and thymol.

On examination of stools taken where the patient had no treatment after being (microscopically) free, the following results were found:

After one treatment the result of examination was negative after 7 months in one case, and after 4 months in another, but was positive after 5 months in a third.

After three treatments, two cases showed a negative result after 3 and 4 months respectively.

Of two cases which received four treatments, one was negative after 4 months, the other positive after 31 months.

Of three cases which received five treatments, the first was negative after 21 months, the second after 3 months; the third was still positive after 2 months.

One case which received seven treatments was negative after 2 months.

Two mental cases of melancholia and senile debility died after the second treatment, but showed no ill effects succeeding the treatment. In no single instance did I find the treatment affect the patients, and on the day following they were able to continue their work in the ordinary way.

It is difficult in such places as this to follow up one's patients as one would wish, and, moreover, the environment of the natives is one in which they are very likely to become reinfected after being free, because of their habits in

going about barefooted and the frequent sores on their feet owing to jiggers, etc. I think, however, that a result showing roughly 89 per cent. of cures in four treatments will justify a trial of the method.

I am indebted to Dr. B. Spearman, M.O.H. Zanzibar, and to his bacteriological department, for their examinations of the specimens of the above cases.

## A SPLINT FOR MEDIAN PARALYSIS.

BY

WALTER MERCER, F.R.C.S.EDIN.,  
EDINBURGH.

PHYSIOLOGICAL rest is a prime necessity in the recovery of a paralysed muscle. This is brought about by the mechanical approximation and retention of its two points of insertion so that its opponent is conversely elongated.

One of the difficulties hitherto in the treatment of a median lesion has been the proper retention of the median small thumb muscles in a properly relaxed position so that regeneration can take place with the greatest chance of success. A majority of cases do not show a satisfactory return to power of the opponens and short abductor of the thumb, as is evident in the number of cases of median lesions with a flat thenar eminence and inability to oppose the thumb to any of the other fingers. This is one of the most important movements in the useful hand, and is necessary for all the fine movements of the hand. Without it the utility of the hand is impaired by at least 30 per cent. As Mackenzie aptly puts it, the thumb represents one blade of a dissecting forceps.

The only method so far of in any way relaxing the short thumb muscles is by means of adhesive strapping applied round the thumb and the ulnar side of the hand. This has two important disadvantages. The skin of the hand, already without its beneficent trophic influence, rapidly becomes irritated and often becomes broken so that the adhesive plaster has to be removed. When wearing the plaster the patient's hand is entirely put out of action and he cannot use it for gripping, while the rubber solution in warm weather runs and becomes caught in anything he may attempt to grip. So irksome is it to the patient that it is usually worn only very intermittently.

The splint to be described has neither of the advantages that its only rival has, for the skin is amply protected by its chamois leather lining, while it in no way interferes with function, but rather aids it in making opposition of fingers and thumb possible.

The splint to be described has neither of the advantages that its only rival has, for the skin is amply protected by its chamois leather lining, while it in no way interferes with function, but rather aids it in making opposition of fingers and thumb possible.

### Description.

The essential part of the splint (called the "Opponeus splint") is a light duralumin plate which extends from the fifth metacarpal to the first and extends the length of the metacarpals except in the thumb, where it is rather longer, going just over the metacarpo-phalangeal joint. The plate is accurately moulded round a cast of the hand which has been made with the thumb in the opposed position in the same axis as the middle finger and with the first metacarpal abducted from the second as far as possible—that is, up towards the face of the patient when the forearm is supinated.

FIG. 1.—Showing the extreme flattening of the hand with the thumb "dash" with the palm and no power of apposition. Short thumb muscles are accordingly stretched.

FIG. 2.—Splint applied. Thumb opposed and opponens and abductor relaxed. In useful position and splint not preventing use.

FIG. 3.—Drawing of the duralumin plate when flattened out. The thumb-piece is attached to the hand-piece at an angle of 150 degrees.

It is in this position that we get complete physiological rest for the small median muscles of the thumb.

The duralumin plate is then encased in leather and with a special pocket for the thumb part. The covering is ordinary glove leather and the lining is chamois. Along the ulnar border is the opening, which is closed after putting on by lacing through eyeholes. The photographs show the efficiency of the appliance. In Fig. 1 the thumb is flat and flush with the hand, giving little hope of any recovery taking place in the muscles. Fig. 2 shows the correct position of rest and also the fact that the hand can be easily used while the splint is worn. A rough drawing of the duralumin splint when flattened out is given to show the shape (Fig. 3).

I have to acknowledge the valuable assistance of Mr. Arch. Young, Forrest Road, Edinburgh, who makes the splint.

## THE RELATION OF SCIATICA TO THE SACRO-ILIAC JOINT.

BY

JOHN COWAN, M.B.,

MEDICAL OFFICER IN CHARGE, MASSAGE AND ELECTRICAL DEPARTMENT,  
MANCHESTER ROYAL INFIRMARY.

SCIATICA is commonly defined as pain in the distribution of the sciatic nerve. Both neuritis and neuralgia of the nerve are included under the term. The most frequent condition giving rise to the pain appears to be a much disputed point. Observers appear to be divided into two schools according to their opinion as to whether neuritis or neuralgia is the more common condition. Gowers' regards all cases with persistent tenderness of the nerve as neuritis, and consequently he considers neuralgia as rare. Oppenheim<sup>2</sup> considers that in most cases the signs of neuritis are absent. Barre and Duprez<sup>3</sup> consider that if pressure on the nerve causes acute pain the case is not one of neuralgia. As most cases have this pain on pressure, these two observers must consider neuritis as the common condition. Holmes,<sup>4</sup> however, points out that the nerve trunks are tender in facial neuralgia when no disease of the nerve can be found.

I have recently reviewed my notes on forty successive cases of sciatica which have been referred to me for treatment, and I have been struck by two facts: The first is the great frequency with which sacro-iliac joint pain is found associated with the nerve pain; I have found the joint pain present in most cases of under six months' duration, but that it tends to disappear, although the nerve pain persists. The second point is that pressure on the sacro-iliac joint, in nearly all cases, causes acute pain down the course of the nerve, which, with pressure on the joint, is much more severe than the pain caused by local pressure on the painful spots down the course of the nerve.

From the above facts I have formed the opinion that some morbid condition in or about the sacro-iliac joint (probably an arthritis or a peri-arthritis) is usually the cause of the pain in sciatica. Further, that the pain is usually neuralgic.

The connexion between the joint and the nerve in cases of sciatica has been noticed by other observers. Barre and Duprez<sup>3</sup> observed the connexion, and coined the term "sacro-iliac sciatica." They also noticed that in early cases there is frequently sacro-iliac joint pain which tends to disappear. Gowers<sup>1</sup> states: "The neuritis (sciatic) often arises by extension of adjacent rheumatic affections of the fibrous tissues, especially that form of 'lumbago' which involves the fibrous attachment of muscles to the back of the sacrum, less commonly in its ordinary site." Probably those cases of "lumbago" were painful sacro-iliac joints and the sciatica was neuralgic.

Gibson,<sup>5</sup> in an analysis of 1,000 cases, found lumbago in 132, but he considers that number too low, as many patients overlook the slight pain owing to the more severe sciatic pain. It is probable that those cases of lumbago were those with painful sacro-iliac joints, as most patients refer to any pain in the lower part of the back as "lumbago."

### Anatomy.

There is a close relation between the sacro-iliac joint and the sciatic nerve. The lumbosacral plexus is the source of origin of the nerve, and it also gives a nerve supply to the joint; a morbid condition of the joint, therefore, would cause referred pain down the nerve. The plexus lies immediately in front of the joint, being separated from it only by the pyri-

formis muscle. A peri-arthritis could, by extension, set up a neuritis of the nerve.

I do not consider that a local neuritis is common, otherwise one would expect most pain to be around the joint instead of down the nerve. On the other hand, in neuralgia the pain is frequently felt at some distance from its source of origin.

### Clinical.

Bending and walking cause severe pain in patients suffering from sciatica. Both these actions cause strain on the sacro-iliac joint. Assuming that there is an arthritis of the joint, an exacerbation of the pain would be expected.

Lasègue's sign (flexion of the hip with knee extended) is used to test for sciatica. This movement not only stretches the nerve, but also puts a strain on the joint; consequently it can be used to test for sciatica, whether due to neuritis or a morbid condition of the sacro-iliac joint.

In cases of sciatica the patient usually obtains almost immediate relief by lying down, especially in the semi-prone position with hip and knee slightly flexed. This is the position in which all strain is removed from the joint. One can readily understand how this position would give relief so quickly if the joint is the cause of the trouble, but it is not so easy to see how it would be obtained if the trouble is neuritis.

### Treatment.

Considering the sacro-iliac joint as the seat of disturbance in cases of sciatica, it has been my custom to apply treatment towards that part and not towards the course of the nerve. The results have been striking in most cases, and could not have been obtained if the joint had not been the cause of the pain.

In early cases, mainly when there is pain in the joint, I have found that radiant heat and massage to the joint is very effective. In older cases I have found that ionization with iodine ions and massage to the joint usually give relief. Anodal galvanism to the painful spots down the course of the nerve can be given conveniently with the ionization. In some cases it is necessary to break down adhesions in the joint; this can be done by Swedish remedial exercises and also by means of the movement which is adopted in nerve stretching.

Recently I have tried diathermy in all cases, and I have found that the results are better than with any other form of treatment, especially in old-standing cases.

### Analysis of Forty Successive Cases of Sciatica.

Of the 40 cases 14 were of less than six months' duration; in 2 of these the pain was situated in the nerve, and in 12 in joint and nerve. There were 26 cases of more than six months' duration; in 15 of these the pain was in the nerve, and in 9 in joint and nerve. There were 2 cases of hip disease.

Duration and Situation of Pain.	Effect of Pressure on Sacro-iliac Joint.			
	Pain in Nerve and Joint.	Pain in Nerve only.	Pain in Joint only.	No Pain.
Group 1: Under six months—in nerve and joint.	11	0	1	0
Group 2: Under six months—in nerve only.	2	0	0	0
Group 3: Over six months—in nerve and joint.	6	0	3	0
Group 4: Over six months—in nerve only.	11	2	1	1
Totals ... ..	30	2	5	1

Three cases showed definite signs of neuritis—namely, muscle wasting, sensory changes, etc. Two of these cases belonged to Group 3, and only gave pain in the joint alone on pressure on joint. One case belonged to Group 4, and gave no pain with pressure on the joint. The 6 cases which did not give any response down the nerve with pressure on the joint did not respond to treatment at all. Of the remaining cases trace was lost of 3, there was no improvement in 2, a cure was effected in 12, and in addition 15 were in different stages of improvement.

### Summary.

Out of 38 cases only 3 had neither signs nor symptoms in the sacro-iliac joint.

Thirty-two cases had a positive response down the nerve to pressure on the joint. Of these cases 21 were improved by treatment of the joint.

In 12 cases out of 14 of under six months' duration there was pain in the joint as well as down the course of the nerve.

In only 9 cases out of 24 over six months' duration was there pain in the joint.

## PORTAL PYAEMIA SECONDARY TO UMBILICAL INFECTION.

BY

G. BRUCE WHITE, M.B., CH.M.S.D.,

HOUSE-PHYSICIAN, ST. GEORGE'S HOSPITAL, LONDON.

SUPPURATIVE phlebitis, as a result of spreading infection from the umbilicus, is rarely seen nowadays. The case here reported is of interest from several points of view, especially as there was no sign of inflammation of the umbilicus when the infant was admitted to hospital sixteen days after birth.

## History.

On November 30th, 1922, when I was house-physician to the Royal Waterloo Hospital, a female infant aged 16 days was admitted at 9 p.m. on account of swelling of the abdomen, first noted twelve hours previously. There had been no action of the bowels for two days, even after a dose of castor oil, and an enema given that morning returned clear. Some blood and mucus had been passed per rectum during the last eighteen hours. The mother stated that the child had had several "convulsions" within a few days of birth, but had appeared healthy until three days before admission, when the skin became yellow. There had been no vomiting.

The infant was fairly well nourished, it was rather deeply jaundiced, and the marked abdominal distension rendered palpation difficult. The umbilicus was perfectly healed, the temperature was subnormal, but the pulse rate was rapid (uncountable). The abdomen was hyper-resonant from distension with gas, the liver was distinctly enlarged, but no other swelling could be detected on palpation. The rectum, the anal canal, and the lower part of the rectum felt swollen and boggy, and the examining finger was streaked with blood.

Mr. Cairns Forsyth saw the child an hour after admission, and the likely causes of the condition were discussed. The onset of the jaundice was too late for physiological jaundice of the newborn, and rather early and abrupt for that due to atresia of the bile ducts. Infection spreading to the liver by the umbilical vein was regarded as improbable, since the umbilicus was soundly healed and the temperature was subnormal. No conclusion as to the origin of the jaundice was arrived at, but since the infant was obviously suffering from intestinal obstruction it was decided that exploratory laparotomy was justifiable.

## Operation.

When the child was under anaesthesia the abdomen was again palpated, but no swelling could be detected. The abdomen was opened by a small paracental incision, the right rectus being displaced outwards. Some clear fluid escaped as soon as the peritoneum was incised and coils of intensely congested small intestine protruded into the wound. No signs of mechanical obstruction of the bowel could be found. The small intestine was everywhere distended, but the large intestine was collapsed. The appendix was normal. The liver was enlarged, of a deep maroon colour, and its lower surface was smooth. The gall bladder appeared normal and bile could be seen in its interior through its translucent wall. As the intestinal obstruction was evidently due to paresis of the bowel, secondary to a grave toxæmia probably of hepatic origin, the abdomen was closed.

## Necropsy.

The child died twelve hours later, and at the autopsy the same general condition of the abdomen was observed, but on cutting through the ligamentum teres to remove the liver pus poured from the umbilical vein, which was widely distended (to three-fourths of an inch). On exposing the liver its upper surface showed a number of whitish areas which on section corresponded to small abscesses within the liver substance. The liver was enlarged and between the infected areas was intensely engorged with blood. There were a number of small haemorrhagic spots scattered throughout the lungs, but no evidence of abscess formation in any other viscera or in the brain could be detected. The lower part of the rectum and the anal canal were much congested and swollen and doubtless accounted for the passage of blood and mucus.

It is highly probable that infection took place in a clot in the umbilical vein and spread to the liver. That the navel should have healed soundly when the intra-abdominal part of the umbilical vein was full of pus is somewhat remarkable. The symptoms from which the child suffered are easily explained by the condition of the liver found at autopsy.

I am greatly indebted to Mr. Cairns Forsyth for permission to report the case.

## EXCISION OF THE FIBULA IN AMPUTATIONS BELOW THE KNEE-JOINT.

BY

CHARLES NOON, F.R.C.S.,

ASSISTANT SURGEON, NORFOLK AND NORWICH HOSPITAL.

SERVICEABLE stumps after amputations of the lower extremity must possess good movement, be painless, and be able to sustain the direct pressure of a part of the body weight upon the artificial limb. Without these attributes it is practically impossible to fit an absolutely satisfactory artificial limb. Much time and money are often wasted in making and attempting to fit artificial limb after artificial limb to unsatisfactory stumps, whereas correct operative treatment before fitting the artificial limb might have saved much time and trouble both to the artificial-limb maker and the patient.

During the last five or six years a great deal has been learned about amputations, amputation stumps, and the fitting of artificial limbs. Some amputations which were before the war considered "first class" have been of late unable to stand the tests to which they have been subjected. There are still probably many amputation cases in the country which require operative treatment before they can be fitted with really satisfactory artificial limbs. Many below-knee amputation stumps which are at present painful and unsound can be transformed into serviceable stumps by excision of the remaining part of the fibula and removal of that part of the external popliteal nerve which lies below the level of the knee-joint.

In a considerable number of cases of amputation below the knee-joint the presence of the fibula appears to cause considerable difficulty in fitting and wearing a satisfactory artificial limb. This difficulty is more especially noticeable in stumps where atrophy of the muscles covering the bones has been excessive. It is well known that structures that do not exert their normal function undergo atrophy, particularly muscles and bones, so that it is easy to explain the excessive atrophy often seen in amputation stumps. It is in these cases especially, where atrophy has been excessive and in which pressure on the prominent head of the fibula causes pain, that removal of the bone improves the condition and produces serviceable stumps.

Although the removal of the fibula has been practised by a few surgeons it does not appear to have received the consideration due to it, taking into account the benefit which is likely to be derived from its practice. The textbooks of surgery scarcely make any mention of the procedure. Muirhead Little in his recent book on *Amputations and Amputation Stumps* (Chapter II, p. 39) refers to the procedure as follows:

"When the amputation is below the knee excision of all that remains of the fibula will add to the amount of skin available, and sometimes enable the surgeon to cover the tibia satisfactorily without shortening it."

In *Orthopaedic Surgery of Injuries*, edited by Sir Robert Jones (vol. I, p. 478), there is the following reference to excision of the fibula in amputation below the knee:

"In these short stumps there is a tendency for the fibula to tilt away from the tibia and project. In these cases it is a good plan to remove the fibula. In this way a piece of bone is removed which stands pressure badly, and at the same time the bulk of the stump is diminished, so that a flap which would otherwise be too small may suffice."

A man with a serviceable stump, fitted with a satisfactory artificial limb below the knee, is often able to earn his living at a laborious occupation which may necessitate him standing for many hours a day and walking long distances in the performance of his duties. The following cases, taken from a large series of amputations which have come under my care during the last five or six years, will illustrate how excision of the fibula has been the means of obtaining serviceable and satisfactory stumps.

CASE I.—Gunshot Wound of Right Leg: Amputation below the Knee: Re-amputation below Knee with Excision of the Fibula. Result, Serviceable Stump.

J. A., a professional golfer, aged 23, was wounded in the right leg on March 16th, 1916, while serving in France; the leg was amputated, and he was transferred to England on April 6th.

Examination (May 1st, 1916).—General condition good. Local condition: The right leg has been amputated below the knee by the guillotine method. The extremity of the stump is covered by a healthy granulating area.

Re-amputation May 5th, 1916. The fibula was excised and flaps were dissected from the anterior and posterior aspects of the amputation stump; the anterior and posterior tibial nerves were cut short and the flaps brought together with a little tension as possible. Four months later the stump was soundly healed. He was fitted with an artificial limb in December, 1916, and the following May he was able to walk and stand with ease and comfort and could play a round of golf over a course of eighteen holes. In this case without removal of the fibula it would have been impossible to cover the ends of the stump with a satisfactory skin flap. Removal of the fibula enabled a satisfactory stump to be obtained below the knee-joint, and a limb could be fitted which gave the patient full use of the knee.

**CASE II.—Gunshot Wound of Right Leg: Amputation below the Knee with Excision of the Fibula. Result, Serviceable Stump.**

A. G., a fish curer, aged 25, was wounded in the right leg in May, 1916. The leg was amputated by the guillotine method, and he was transferred to England. The stump below the knee measured 2½ inches, and its extremity was covered by a layer of healthy granulation. Three months after the primary amputation a second amputation was done: the fibula was excised, the external and posterior popliteal nerve dissected out and cut as short as possible, and skin flaps were freed and brought over the stump with as little tension as possible. In six months' time the stump was completely healed and ready for fitting with an artificial limb. The patient was given his first limb in January, 1917, and his second limb in September, 1919. He has returned to his previous occupation as fish curer, and can walk two miles to his work, stand all day, and has no pain or discomfort in the stump.

**CASE III.—Gunshot Wound of Left Leg: Amputation below the Knee: Painful Stump, Unable to Bear an Artificial Limb: Re-amputation with Excision of Fibula. Recovery with a Serviceable Stump.**

H. M., aged 33, was first seen in March, 1922, when he gave the following account of himself. He joined the army in 1915, and served in France until he was wounded in the left leg in November, 1916. He passed through the various hospitals in France and was finally transferred to England and was admitted to a hospital in Sheffield, where his leg was amputated; the amputation was followed by two re-amputations to prepare the stump for the fitting of an artificial limb. He was fitted with his first artificial limb in March, 1917, and with his second in 1920. He states that neither limb has ever been satisfactory. He could at the best only wear the limb for three or four hours a day, and could only walk about half a mile with difficulty. At various times, owing to the pain and swelling, he has been compelled to leave off the artificial limb and take to crutches for two or three weeks at a time.

*Examination.*—A healthy-looking man; the left leg has been amputated and he walks with difficulty on an artificial limb. Local condition: The left leg has been amputated below the knee. The stump measures 4 inches in length. The soft tissues covering the stump are redundant. The fibula is prominent and pressure over the head of the bone causes much pain.

Removal of the remaining part of the fibula with the redundant soft tissues was advised. The operation was performed under chloroform on March 14th, 1922. A vertical incision was made over the outer aspect of the stump, the incision being a quarter of an inch behind the fibula and carried downwards over the lower end of the stump. The external popliteal nerve was exposed, dissected free, and after crushing as high as possible with strong lever compression clamps divided through the crushed area and allowed to retract. The fibula was then removed subperiosteally and the redundant tissues at the extremity of the flaps removed. A few bleeding points were ligatured, the skin sutured, and a firm gauze bandage applied. The stitches were removed on the seventh day, and the patient allowed to get up at the end of two weeks. In order to prevent the swelling of the stump which so often happens in cases of amputation and re-amputation a light plaster-of-Paris bandage was applied to the stump over a small dressing. It has been found that this procedure effectively prevents swelling of the stump, lessens pain, and allows the early application of an artificial limb.

This patient was fitted with an artificial limb early in May; he rapidly got used to the limb, and he has had no pain or difficulty in wearing it since the operation of removal of the fibula, and now, four months after the operation, he can wear the limb all day and walk four or five miles without difficulty or pain.

**CASE IV.—Gunshot Wound of Right Leg: Amputation below Knee: Painful Stump, Unable to Wear Artificial Limb: Re-amputation with Excision of the Fibula. Serviceable Stump.**

J. S., aged 42, was first seen in April, 1922, when he complained of a painful stump and inability to wear his artificial limb. He gave the following account of himself. The left leg was amputated below the knee in April, 1918; an attempt was made to fit him with an artificial limb in December, 1918, and he was supplied with a second limb in 1919. He has never been able to get about with any comfort and many attempts have been made to try and fit him with an artificial limb, without any permanent success. He has never been able to walk more than half a mile, and the stump was always painful.

*Examination.*—General condition good. Local condition: The right leg has been amputated below the knee; the stump measures 3½ inches. The tissues covering the extremity of the stump are adherent to the bones. The fibula is prominent, especially at its lower end, where it is thickened and projects and appears to be tilted away from the tibia. Pressure over the fibula is painful. Removal of the fibula was advised. The operation was done in May, 1922; the fibula was removed and the adherent scar freed

from the bone. The patient was refitted with an artificial limb in June, and since then he has had little or no pain, and has been able to wear an artificial limb with much more comfort.

**CASE V.—Gunshot Wound of Right Leg: Amputation below Knee: Painful Stump, Unable to Wear Artificial Limb with Comfort: Excision of Remaining Part of Fibula. Result, Serviceable Stump.**

F. E., aged 26, was wounded in the right leg in 1917. The leg was amputated below the knee, leaving a stump 3 inches in length. An artificial limb was fitted in 1918, and he was supplied with a second limb in 1919. He states that he has made good use of the artificial limbs, wearing them all day and walking with comfort until about six months ago, when he began to have pain in the stump and experienced difficulty in wearing the limb.

*Examination (July, 1922).*—Local condition: The right leg has been amputated below the knee-joint; the stump measures 3 inches in length. There is some wasting of the tissues covering the stump, but the tibia is well covered. The fibula, which has been divided on a higher level than the tibia, projects on the outer aspect of the stump; the scar is adherent to it, and there is a small bursa over the bone. Pressure over the fibula causes pain.

Excision of the remaining part of the fibula was advised. The operation was done on August 9th. The wound healed well and the artificial limb was fitted three weeks later. The patient now walks well and is free from pain.

**CASE VI.—Gunshot Wound of Left Leg: Amputation below the Knee: Painful Stump, Unable to Wear Artificial Limb: Excision of Remaining Part of Fibula. Result, Serviceable Stump.**

W. D., aged 26, was wounded in the left leg in 1917. The left leg was amputated below the knee. He complains that, although fitted with artificial limbs which he has been able to wear, he has never been really comfortable for any length of time. He considers that the artificial limbs with which he has been supplied fit well and that it is the pain in the stump which prevents him from wearing them.

*Examination.*—The left leg has been amputated below the knee. The stump measures 4 inches in length; the fibula is unduly prominent and the muscles covering the stump are wasted. The scar is adherent to the tibia.

Removal of the fibula with freeing of the adherent scar was advised. The operation was willingly agreed to and was performed on March 26th, 1922. The wound healed by first intention, and five weeks later the patient was fitted with an artificial limb. The stump was now painless, with a result that he could walk and stand with comfort.

Removal of the fibula adds so much to the efficiency of stumps after amputation below the knee that I think it is an advantage to perform it in all cases in which the stump will not measure more than four inches.

## BRONCHIECTASIS WITH UNUSUAL COMPLICATIONS.

BY

IVOR J. DAVIES, M.D., M.R.C.P. LOND.,

PHYSICIAN WITH CHARGE OF OUT-PATIENTS, KING EDWARD VII HOSPITAL, CARDIFF.

In the issue of the BRITISH MEDICAL JOURNAL for June 5th, 1920 (p. 767), I referred briefly to two instances of certain complications of bronchiectasis which apparently had not been recorded up to that time, and which can now be described in more detail, as the second case terminated recently.

### CASE I.

The first case was one of bronchiectasis in a man of 46, of pneumonic and pleurogenous origin, in which the necessary usual sinuses became infected in turn, requiring operation for empyema of the antra of Highmore. The fetid pus from the pulmonary cavities was often expelled in quantity and projected suddenly with much force into the mouth and nose, and infection of the accessory sinuses arose in this way. The patient frequently complained of severe frontal headache, which probably resulted from a chronic inflammatory state of the mucosa of the frontal sinuses. Severe attacks of haemoptysis occurred from time to time, and death took place after fourteen years from pneumonia and gangrene of the lung.

### CASE II.

The second case was that of a man, aged 59, of vigorous build and sound health up to the time of an attack of pneumonia and pleurisy seven years previously, after which time he suffered from a chronic cough, profuse purulent expectoration, and gradual failure of health. He was able to hold a responsible position, which necessitated much travelling, in connexion with a railway, to within a month or so of death. He had several attacks of pleurisy (and probably pneumonia) during the course of the disease, which he always attributed to a chill. He was thus susceptible to the septic complications of the disease from the nature of his vocation. The exact situation of the multiple lesions of the disease was indefinite, probably owing to the associated fibrosis and emphysema of the lungs and

to pleural adhesions over the lower lobes. The main lesions appeared to be in the upper and lower lobes of the right lung. The sputum was examined on several occasions for tubercle bacilli, with negative results. He had never suffered from syphilis, and the Wassermann reaction was negative. He indulged very moderately in alcoholic beverages and tobacco. The disease lasted for close on ten years, when death took place from bronchopneumonia.

The complications which chiefly deserve notice were a condition of chronic glossitis, and a persistent severe albuminuria from chronic nephritis, both of which were probably of toxic origin from chronic infection.

The patient was seen regularly over a period of three years up to the time of the termination. The general state of his health and nutrition was fairly well maintained, despite the secretion of a fair amount of purulent sputum daily and the presence of well marked albuminuria. There was a slight degree of cyanosis with but slight clubbing of the fingers. His tongue from the time when he was first seen was large, red, and unhealthy-looking, being deeply fissured. After coughing, and even on lightly wiping the tongue, the fissures were occupied and filled by expectorated purulent material. A condition of chronic glossitis undoubtedly arose from direct contact with the pus expelled from the lungs, and, despite careful cleansing with antiseptics, the tongue remained enlarged and chronically inflamed, with but slight inconvenience in the form of some local discomfort. There was no undue arteriosclerosis, no cardiac hypertrophy, and the systolic blood pressure never rose above 160 mm. The fundus oculi was normal. No oedema was observed.

The urine was examined on several occasions by Dr. R. L. Mackenzie Wallis of St. Bartholomew's Hospital, with the following results: The colour was pale. The quantity throughout was only a little in excess of normal and was well maintained up to the time of death. The reaction was acid. The specific gravity declined from 1020 in the earlier reports to 1014 a few weeks before death. The albuminuria was considerable and varied from 0.35 gram per cent. (Aufrecht) to 0.75 gram per cent. shortly before death. Globulin was usually present in too small a quantity for accurate estimation, but was approximately 0.65 gram per cent. on one occasion, and the ratio of albumin to globulin was about 8:1, which figures agree closely with those found in ordinary nephritis. Sugar, blood, acetone bodies, and urobilin were absent. Indican was present, from a trace in the earlier stages to a strongly positive reaction in the terminal stages of the disease. The total acidity was from 52.4 per cent. N/10 NaOH to 47.2 per cent. N/10 NaOH. Ammonia was present, from 0.05 gram per cent. to 0.03 per cent. The urea concentration test after the administration of 15 grams of urea gave a figure of 1.4 per cent. urea, whereas the urine a few weeks before death contained 2.1 per cent. urea, on a fairly liberal diet. The diastase content was usually 5 units, but was 10 units in 1921, six months before death. Microscopically, pus cells were present in fair number in the earlier stages, but became fewer in the later stages. Red blood cells were absent. Epithelial cells were usually present. The casts were generally of the granular and hyaline variety, and no epithelial and fatty casts were found at any time.

The low urea concentration and the low diastase figures in the earlier stages suggested renal inefficiency, but later examinations did not confirm this view, and shortly before death the urea percentage was normal. Blood urea tests were not performed. There was no evidence of uraemia or of its minor manifestations, so that the kidneys were probably not seriously affected despite the severe degree of albuminuria. The renal condition was probably one of toxic nephritis from septic absorption, for there was no evidence of lardaceous disease of any other organ, such as the liver, spleen, or intestines. The characters of the urine were more those of nephritis than of lardaceous disease, more especially in the absence of polyuria and of a urine of low specific gravity. No other septic complications occurred, and haemoptysis was absent throughout. No post-mortem examination was made.

I am indebted to Dr. Mackenzie Wallis for his reports, and to Dr. B. Barnard of Machen, Mon., for valuable information in the case of the second patient.

THE tenth congress of French-speaking anatomists and histologists will be held at Lyons from March 25th to 29th, under the presidency of M. Lesbire, professor at the Lyons Veterinary School.

THE second International Congress of Comparative Pathology will be held at Rome from October 7th to 14th. Medical men, veterinary surgeons, botanists, and biologists who propose to attend should communicate with the President of the Congress, Professor E. Perroncito, 40, Corso Valentino, Turin.

THE eighth French Medico-Legal Congress will be held in Paris from May 24th to 26th, under the presidency of Professor Pariset of Nancy. A discussion on international legislation to control the sale of cocaine will be introduced by Professor Courtols-Suffit. Injuries of the vertebral column by industrial accidents and the law of industrial diseases will also be discussed.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### A CASE OF ADDER BITE.

I HAVE written out these notes at the suggestion of Sir Thomas Oliver, whose paper on adder bite was published in the BRITISH MEDICAL JOURNAL of December 9th, 1922 (p. 1114).

A boy aged 6 was brought to my house at Helston, Cornwall, in the autumn of a year between 1906 and 1910. While picking blackberries he had been struck by an adder at a point half-way between the base of the nail and the last joint of the right index finger. He walked half a mile home, was dressed in his Sunday clothes, and walked again to the station about half a mile away; then came four miles by train, and walked another half-mile down to my house. During the latter part of the journey he was exceedingly sick. My waiting-room was full, and it was not till he had been in the house half an hour or so that I was told a child had fainted. When I saw him—some two and a half or three hours after the bite—he was lying on the floor, blanched and sweating profusely and practically pulseless. With an injection of strychnine, hot bottles, etc., he gradually revived, and after he had had a stiff glass of brandy and milk I was able to put him in my car and drive him home. Two tiny punctures were just visible at the time of my first examination. By the time he reached home the arm was swollen and he was semi-conscious, and moaning with pain. Hot fomentations from hand to shoulder seemed to relieve this somewhat. The semi-conscious condition lasted about two days.

The morning after the bite, when the late Dr. Edward Permerman of Redruth saw the child with me, the right arm was swollen to the size of his thigh, the skin deeply mottled with all the colours of the rainbow, the swelling and discoloration extending across the chest in front. Next day the swelling extended across the chest back and front, and down the arm to the elbow. There was some swelling of the root of the neck, but not enough to cause any difficulty in swallowing. The limitation of the discoloration was most marked. It did not extend to the neck, and was bounded below by a line drawn round the chest at the level of the lower part of the axilla.

From that time the child gradually improved, the swelling and colour dying down, and in about a fortnight he was quite restored to health.

Owing to the length of time that had elapsed before I saw him, local treatment was useless, but as a matter of precaution I incised the punctures and rubbed in some disinfectant. I think potassium permanganate. The child was so collapsed when I first saw him that I did not expect him to rally, and he must have had an exceedingly narrow escape from death.

The case impressed itself very deeply on my memory, and, though my original notes are lost, the above account is substantially correct as to the time when the various symptoms appeared.

In spite of the large number of adders to be found in Cornwall, this was the only case I heard of where a human being was bitten. I was told that when a lane was being cut through the gorse on a moor near Helston to make a 500-yards shooting range, 160 adders were killed. I asked a farmer once to get me some specimens, and he brought in five which he killed in a few minutes on the sunny side of a hedge one April morning. Personally, I had three very narrow escapes from being bitten when shooting and fishing, while my son has twice been struck on the foot. Hounds hunting at the end of the season, when the adders were sunning themselves after emerging from their winter torpor, were frequently bitten, but I believe always recovered. A terrier of mine was bitten under the jaw. The neck and face swelled up very much and the dog was unable to open its mouth for some days, and had to be fed on milk and brandy with a teaspoon. Except for deafness on the injured side, there was no after-effect. Years ago a nephew of mine, when in the *Britannia*, picked up an adder while ashore, and put it in his pocket and forgot it. Later on he put his hand in his pocket to see if the beast was still there, and was bitten on the ball of the thumb. I know no details, but remember that the boy was exceedingly ill and his people had to be sent for.

Northwich.

MARK R. TAYLOR.

#### TRIANGULAR FRONTAL HYPERAEMIA IN INFANTS.

CERTAIN infants and young children display a phenomenon which has not, I believe, hitherto been noted in medical literature. It consists of a triangular area of hyperaemia situated over the juncture of the two frontal bones and extending from the anterior fontanelle above to the nasion

below—the base of the triangle being above and the apex, which is usually blunted or irregular in outline, being below. The width of the triangle varies, but across its centre it averages from three-quarters to one inch. The area is usually punctate in appearance, and at birth is of a bright red colour, the latter gradually fading as time goes on, to become eventually just a faint blush before finally disappearing altogether at or about the end of the second year. Occasionally the macules—which are not elevated—are replaced by streaks, and the colour may be deep enough to border on purple, and so set up the impression in the minds of the parents that the child has a birth mark, but I have never known one of these patches to remain visible for very long after the end of the second year. In some instances the colour is faint at the outset and disappears entirely in a month or two.

This peculiarity has been noted in both sexes and in dark as well as in fair children; it is comparatively common—2 out of 41 children examined on one day, and 3 out of 66 examined on another day, showing it; and it appears to be of academic interest only, no practical difference having been noted between those children who show it and those who do not.

A. F. G. SPINKS,  
Maternity and Child Welfare Medical Officer,  
Newcastle-upon-Tyne.

## Reports of Societies.

### DISRUPTIVE PHENOMENA IN GUNSHOT INJURIES.

A MEETING of the Pathological Section of the Royal Society of Medicine was held on February 20th, with Professor LUDINGHAM, the President, in the chair, when Professor S. G. SHATTOCK read a paper on the disruptive phenomena in gunshot injuries and their physics.

Professor Shattock observed that whatever clinical peculiarities gunshot injuries presented, their proper pathological interest, as injuries only, was limited to the fact that the velocity of the missiles produced special effects known as explosive, or better as disruptive. As was well known, Professor Vernon Boys some years ago succeeded in photographing bullets soon after their leaving the rifle, and demonstrated the presence of a conical air wave accompanying the missile. At first the displacement of air seemed of some importance, but it was quite negligible, although under the name of "windage" much had once been attributed to it. Amongst other proofs the speaker had found that, on firing with a service rifle and pointed modern British bullet, at 20 feet, through screens of tissue paper tensely stretched on wooden frames, the aperture in the paper very little exceeded the diameter of the missile.

The late Sir Victor Horsley attributed the disruptive effect chiefly to the factor of the spin of the bullet. A close study of the casts made from the cavities produced in soft clay by firing directly and at close range into the latter did not, in the speaker's opinion, confirm the evidence of this; the ridges on such casts presented only slight indications of any obliquity, and not more than due to the open spiral of the rifling. The most conclusive proof of the absence of spin was furnished by the study of British bullets fired into sand: the apex showed fine scratches due to the sand, which were not spiral but longitudinal. The disruptive factor was thus reduced to that of forward velocity acting upon a mobile and practically incompressible medium, the lung alone being excepted, in which no such disruption took place owing to the compressibility and ready escape of its contained air. The lateral disruptive movement was imparted to the medium by the intense compression in front of the bullet, which compression was also exerted more directly sideways by the conical point simultaneously acting as a wedge. It was in the skull that the disruptive phenomenon was most marked. The effect was still often supposed to be hydrostatic, but it was a hydrodynamic one, as shown by experiments made upon objects provided with a free exit—upon tins empty and others filled with water freely open at the top: two clear circular holes were made in the first; in the others the back was split into large triangular everted flaps. The rate of the wave transmitted by the incompressible water was equal to that of the bullet, which, as soon as it impinged, was accom-

and filled with water; if the brain were left *in situ* in the inverted skull the same comminution took place.

It had been asserted, by Professor Stargardt in 1914, that the British rifle bullet was designed for expansion; that, on striking, the momentum carried the leaden core over the aluminium cone, and split the mantle. A study of bullets fired experimentally through calvariae of different thicknesses, the bullets being recovered in cotton waste behind, showed that on perforating dense bone the momentum on impact caused the lead to splay out or mushroom at the open base, and not at the junction of the lead and aluminium. In the first degree the mantle was evenly turned back over a projecting rim of the lead; in the later the mantle was split and turned out or recurved, like the sepals of a fuchsia, the splitting starting at times when scored by the rifling. On compressing bullets in a vice some of the lead was expressed from the open base, but no displacement occurred over the harder aluminium cone. The cupro-nickel mantle of the British bullet, however, was less resistant than the German, of steel. This the speaker was able to show by taking equal lengths of the two, placing a steel ball over the open end, and testing by increasing loads the pressure they would withstand. The British mantle began to yield or open out under a load of 180 lb.; the German, under a load of 390 lb.

#### The Fermentative Reactions of *B. diphtheriae*.

Dr. C. C. OKELL and Miss E. M. BAXTER read a paper on the fermentative reactions of *B. diphtheriae*. They had examined the fermentative reactions of the serological types of virulent *B. diphtheriae* described by Eagleton and Baxter, as well as their unclassified cultures. The most useful agents for differentiating the *B. diphtheriae* appeared to be glucose, saccharose, lactose, dextrin, glycerin, and litmus milk, and glucose and saccharose appeared to be the sugars of most practical use in differentiating the diphtherial from the diphtheroid groups. All the serological types of virulent *B. diphtheriae* so far examined had practically identical sugar reactions. Fermentative reactions at present available could not be used to distinguish between the various serological types or between virulent and avirulent forms.

#### The Inheritance of the Specific Iso-agglutinable Substances of the Red Blood Cells.

Dr. S. C. DYKE communicated the results of an investigation undertaken by Dr. C. H. Budge and himself in the maternity ward of St. Thomas's Hospital into the inheritance of the specific iso-agglutinable substances of the red blood cells. Ninety-seven unions were observed with 98 offspring. In no case was it found that the iso-agglutinable substances A or B of the red cells appeared in the offspring without having been previously present in the blood of the parents, this being in conformance with the hypothesis of von Dungern and Hirschfeld. Placental blood was used for ascertaining the blood group of the infants; it was found that in only 16 out of the 98 cases investigated was it possible to allot the placental blood to its group by means of the agglutinins of the serum; in the remaining 82 the agglutinins were either completely or partly absent. In determining the group of the offspring reliance was consequently placed upon the reaction of the red cells. It was pointed out that 32 of the 98 babies examined appeared to be of a different group from their mothers.

#### Carcinoma of the Skin in Rabbits.

Dr. J. A. MURRAY showed preparations of two squamous-celled carcinomata of the skin which he had produced in rabbits as the result of eight months' painting with an ethereal extract of tar. The latent period of the development of these tumours corresponded fairly closely with that seen in the mouse. Dr. Murray said that they were likely to prove of great value in the investigation of therapeutic measures, for the rabbit was a particularly favourable animal for that purpose.

#### PRIMARY UNION IN SUPRAPUBIC OPERATIONS.

A MEETING of the Urological Section of the Royal Society of Medicine was held on February 22nd, with Sir JOHN THOMPSON-WALKER in the chair. Mr. RALPH THOMPSON read a paper on the propriety of attempting primary union in cases of suprapubic operations on the bladder and prostate. Mr. Thompson first described in some detail thirty-one cases in which he had performed primary union after suprapubic my, and which he classified under the seven following

headings: simple adenoma of the prostate, malignant disease of the prostate, simple adenoma of the prostate with calculi, growths of the bladder, vesical calculi, retrograde catheterization, and exploration. In seven of the thirty-one operations there followed slight leakage. Mr. Thompson was careful to emphasize that by leakage he meant some damping of the dressing and not suppuration. In twenty cases there was no leakage. Four died, one certainly from causes unconnected with the operation. The average post-operative stay in hospital in cases of simple adenoma of the prostate with primary union was twenty-nine days. The average stay in Guy's Hospital of ten non-selected cases (apart from fistula), in which the wound was left open was 45½ days. He suggested that the closing of the wound caused a much shorter convalescence. In none of his cases was there a fistula persisting after ten days. The dressing bill was materially lessened. In malignant cases there was no post-operative spread of the growth to the skin. He thought that in certain cases primary union should not be attempted. Amongst these were some which involved a wound in the base of the bladder, excluding prostatectomy; cases of rough spiky calculi and a large prostate; cases where the pulse was not good enough to make reactionary haemorrhage improbable; and, naturally, cases with cystitis or uraemia.

Mr. Thompson then described the steps of his operation. He thought that, in spite of anatomical textbooks, the peritoneum appeared in front and at the sides of the distended bladder. He made a transverse incision through the bladder wall. Deep chloroform was the anaesthetic of choice. He invited discussion on the question of preliminary distension of the bladder and of the use of the retractor in badder surgery. He did not use one himself, preferring to bring the growth to him rather than to operate in the depths of a deep and dark pit. He believed it right to attempt primary union in suitable cases because of the comfort of the patient, the shorter convalescence, and the more normal anatomical result. Moreover, he thought that the surgeon probably took more care over the operation if he knew he was about to suture the viscus.

Mr. NICH approved the method, but emphasized the danger of haemorrhage in the closed organ. He believed the indwelling catheter led to epididymitis. The transverse incision gave more room, but every case should be treated on its own merits.

Mr. MONSON did not agree with the method in any case in which degenerative changes of the urinary tract were present. Degeneration meant an increased risk of sepsis.

Mr. JOCELYN SWAN preferred to drain. In his experience most cases sutured after prostatectomy had to be reopened for drainage. He did not think convalescence was much shortened. Usually by the old method the wound was healed in seventeen days and the patient was able to leave hospital seven days later. He used the retractor. He believed that often the growth could not be drawn up in the way Mr. Thompson had suggested.

Mr. MACALPINE liked to close the bladder in three layers, and suggested a method of maintaining the indwelling catheter in position by transfixion of penis, urethra, and catheter. He suggested the treatment of epididymitis by atropine.

Sir JOHN THOMSON-WALKER did not think primary suture made convalescence much shorter, but there was certainly less chance of hernia. Moreover, sepsis was often introduced along a drainage tube; and this was, in primary union, prevented. On the other hand, drainage was not so easy with a catheter as with a tube, and there might therefore be more danger of an ascending infection.

Mr. THOMSON briefly replied and the discussion closed.

Mr. R. OGIER WARD described a remarkable case of air embolism occurring in the course of urethroscopy. The patient was a male, aged 68. Consequent upon gonorrhoea forty years previously he suffered from a stricture in the urethral bulb. During aero-urethroscopy, in which slight bleeding occurred and in which rather more than usual air pressure was necessary, the patient suddenly became dyspnoeic, cyanosed, convulsed, and died. Cardiac massage failed to revive him. The heart could be felt to contain air, and froth issued from the right ventricle when it was later incised. Post mortem all the chambers of the heart contained frothy blood. Bubbles of gas were found in the aorta, common iliac arteries, the pulmonary vein, inferior vena cava, and other vessels. No froth was discovered in the pulmonary artery.

The case was exceedingly interesting, since it demonstrated the danger of aero-urethroscopy with laceration of the mucous membrane of the urethra and a tight stricture preventing the escape of air into the bladder. Mr. Ogier Ward suggested that the employment of oxygen might give a greater margin of safety.

Sir BERNARD H. SPILSBURY said that in his experience the danger of air embolism depended on the size of the vein and its proximity to the heart. Doubtless small air emboli were quite common. Perhaps the right auricular appendage might serve, in the recumbent position of the body, as a safe receptacle for such air during absorption.

### SUBACUTE INFECTIVE ENDOCARDITIS.

At a meeting of the Cardiff Medical Society held on February 13th, with the President, Professor E. J. MACLEAN, in the chair, Dr. IVOR J. DAVIES read a paper on subacute infective endocarditis based upon a report of eight cases. The term was applied to cases of old endocarditis with an added subacute infective process of streptococcal origin. There had been an apparent increase in the disease recently.

Clinical data were submitted in support of Poynton's view that no hard and fast line could be drawn between simple endocarditis and infective endocarditis. In four cases an arthritis of the larger joints was present, indistinguishable from that of subacute rheumatism. In one of these cases the post-mortem appearances resembled those of simple endocarditis, except that there was an extension of the morbid process to the wall of the left auricle. The clinical picture was described as briefly that of a case of valvular disease, usually aortic in the case of ex-service men, with certain general signs and symptoms added to those of the mechanical cardiac disability. These were grouped under two heads: (1) toxic; (2) embolic. The former included a low grade of irregular, remittent fever, which might be absent for days or weeks. A chart was shown in which the temperature was normal for a period of five weeks except for two elevations to 101° and 100°, separated by an interval of eighteen days, after which the typical low irregular fever was resumed. The onset of pallor, particularly in a case of aortic regurgitation, was emphasized as an early indication of a general infective process, which was also disclosed through loss of flesh and strength. Enlargement of the spleen was perhaps the most valuable early sign indicating that a general infective process had been added to the old condition of valvular disease. Clubbing of the fingers, too, occurred early in the disease. The embolic signs shown by the eight cases included petechiae, a papular and nodular eruption, mycotic aneurysms of the femoral and brachial arteries, intermittent albuminuria, and haematuria. The duration varied from three months to two years, and was on an average twelve months. The extension of the morbid process from the mitral to the aortic valve was observed in one instance. The mitral valve was badly affected on admission, the aortic valve being apparently normal, as the sound of its closure was clear and sharp. The second sound then became indistinct, later a bruit or squeak appeared, and afterwards a musical diastolic murmur was audible up to the time of death. Necropsy showed one cusp of the aortic valve badly affected, being almost entirely destroyed and replaced by vegetations, one of which was sessile and, during life, gave rise to the musical murmur. The inner end of the third left space was described as the optimum point in auscultation for evidence of early aortic incompetence, as was to be expected from the regional anatomy of the valve. Vaccine and serum therapy, as in other forms of septicaemia, appeared to be the most promising line of treatment. Death occurred from heart failure, except in two cases in which acute uraemia was the final event. In diagnosis the general disturbance, clubbing of the fingers, and enlargement of the spleen were the important early signs of the disease. A daily examination of the urine, particularly of the deposit, for blood cells would sooner or later show that embolism has occurred. Blood culture might show the streptococcus, and if negative from venipuncture, then a little blood could be withdrawn from the spleen for cultural examination.

Dr. R. PRICHARD stated that in his experience of subacute infective endocarditis there had been, in most of his cases, an antecedent history of rheumatism. He was of opinion that an infection of intestinal origin played an important part in the subsequent development of the condition; he had

frequently noted the presence of tympanitis and general atony of the bowel, and he had succeeded in obtaining temporary improvement of the cardiac state following the administration of intestinal antiseptics. In one case the etiological factor of pyorrhoea alveolaris was strikingly demonstrated; removal of the teeth was followed by relief of the valvular symptoms, and the man's condition so improved that at the end of six months he was sent back fit for light duty.

The PRESIDENT asked if the condition occurred more frequently in one sex than the other, and if auricular fibrillation had been present in any of the cases.

Dr. H. A. HAIG's contribution to the discussion was based on the post-mortem examination of 30 cases seen at a pensions hospital during 1920-21. The majority showed a streptococcal infection of either the aortic valve or the aortic and mitral valves together. In a few cases *S. haemolyticus* had been proved by blood culture to be present during life. Regarding antecedent conditions in the heart valves, especially the aortic, the question of a specific history was raised. Throughout the series of cases the kidneys were the seat of lesions referable, he considered, to the slowly acting toxæmia directly connected with the infective process. The lesions took the form of (a) a diffuse interstitial fibrosis, associated with hyaline change in partially and completely fibrosed glomeruli, and thickening of the intima and sometimes of the media of the smaller arteries; (b) collections of lymphocytes both immediately under the capsule and in the cortex; (c) at times an advanced degeneration of the epithelium lining the convoluted tubules; sometimes dilatation of the tubules had occurred with desquamation of the lining epithelium. (d) Small subcapsular haemorrhages, and an engorgement of the renal vessels generally; the subcapsular haemorrhages appeared to be of the nature of small multiple infarctions. These changes did not occur together in the same kidney, sometimes one type, sometimes another, being predominant. There was a possibility, he agreed, that some of the changes, especially in the glomeruli, were due to an antecedent attack of trench fever. On the other hand, the evidence of recent mischief pointed directly to the involvement of the kidneys in the general process. He mentioned the further possibility of war wounds having acted as portals of entry for the systemic streptococcal invasion.

Dr. HENRY EVANS related a case of subacute infective endocarditis where he had been able, also, to trace the secondary involvement of the aortic valve from the mitral. He quoted Cotton to the effect that the earliest manifestations of petechiae were to be noted under the finger-nails and in the subpalpebral conjunctiva.

Dr. IVON DAVIES, in reply, agreed with Dr. Prichard in regard to the value of treating any coexisting alimentary intoxication. He assured the President that the condition was equally common in both sexes, and that auricular fibrillation was an infrequent event. He disagreed with Dr. Haig regarding the renal lesions, being of opinion that diffuse nephritis occurred in acute infective endocarditis rather than in the subacute variety. Further, he stated that there was no reason for believing that war wounds played any prominent part in the etiology of the latter process, and that although in one of his series of cases the onset of the condition was said to date from a fall, accompanied by superficial abrasions, he was not prepared to admit any etiological significance therefrom.

#### Undile Tears.

Mr. J. W. TUDOR THOMAS gave a demonstration, illustrated by cultures, of the bactericidal action of tears. Basing his work on the technique of Fleming, with various modifications, he showed that both fresh and boiled tears killed young cultures of *Sarcina flava* in dilutions of 1 in 1,000. He further showed that heating tears to dryness and redissolving the residue had no effect on their bactericidal properties. Undiluted tears killed *Staphylococcus albus* and inhibited its growth in dilutions of 1 in 40. No bactericidal action was noted in the case of *Bacillus coli*, *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Bacillus pyocyaneus*. It was suggested that in estimating the sterility or otherwise of the conjunctiva the material obtained should be diluted appropriately in order to neutralize its bactericidal action; the latter would appear to be either organic in nature or closely bound up with the albumin molecule in the tears. It was improbable that this was in the nature of an enzyme, since its action remained after boiling.

#### Lipoma.

Dr. H. SHEASBY showed a boy, 8½ years old, with a large swelling in the right thigh, which first appeared at the age of 2½ years on the outer surface of the middle third of the thigh, and had since got gradually bigger. There was slight pain when the leg was fully flexed. For three months it had been treated as a tuberculous lesion, but aspiration was negative and a skigram showed no implication of the femur. The general opinion was that the condition was due to a lipoma underlying the quadriceps extensor.

### DIPHTHERIA CARRIERS AMONG CHILDREN OF SCHOOL AGE.

At a meeting of the Medical Officers of Schools Association on February 23rd, Dr. J. GRAHAM FORBES gave an account of investigations on diphtheria carriers among London school children. He mentioned that the prevalence of diphtheria in London during the years 1920-22 had surpassed all previous records, and for any approach to it, it was necessary to go back to the eight-year period 1893-1901. The number of cases began to rise in the second half of 1919, reached its height in the last quarter of 1921, and diminished but little in 1922. The figures for the three years were as follows:

Year.	Total Cases Notified.	Cases of Children of School Age (5 to 15 years).
1920	13,780	6,499
1921	16,319	9,089
1922	15,287	7,352

During each of these years some two hundred or three hundred special visits of inspection were paid to the schools on account of diphtheria alone, and the bacteriological examinations of the throat and nose of children swabbed in the course of these special school visits gave the following results:

Year.	No. of Examinations.	Negative.	Positive.	Suspicious.
1920	5,811	4,740	721	350
1921	6,606	5,541	656	409
1922	5,401	4,543	488	370

The epidemic appeared to have radiated from a focus in the contiguous areas of Stoke Newington, Hackney, and Islington, and in 1922 to have been concentrated in the south-western districts (Battersea and Wandsworth). From April, 1921, the virulence test, as to the value of which the speaker was most emphatic, was applied, and in 553 examinations of carriers (387 children) in which the *B. diphtherias* was isolated, the cultures proved to be virulent in 343 (260 children) and avirulent in 210 (127 children). The proportion of the virulent carriers to the total number in the case of these school children was, therefore, considerably above the proportion (38.8 per cent.) given in Dr. A. J. Eagleton's series, published in the BRITISH MEDICAL JOURNAL of January 28th, 1922 (p. 139). Of these 387 carriers 243 gave evidence of throat and nose defects, and of those giving such evidence 168 were found to be in the virulent category and 75 in the avirulent. The cases with a previous history of diphtheria numbered 16, and among these the strain was virulent in 12 and avirulent in 4. There was a history of sore throats and colds in 53 cases, of which 35 were virulent and 18 avirulent. Home contacts of diphtheria cases numbered 35 (virulent 25, avirulent 10), and desk contacts at school 19 (virulent 14, avirulent 5). Dr. Forbes regarded the virulence test as extremely useful because under proper precautions those reported avirulent could be readmitted to school, whereas in the absence of such a test they might have remained excluded for months. Some cases had been carrying for as long as three years, and on being found avirulent were readmitted to school, without harmful result. So far as could be ascertained, the organism remained true to its type of virulence or avirulence. It was recognized, however, that virulent and avirulent strains might coexist, and this had, in fact, been found in two cases among the 387 children. Very rarely the strains might alternate, but the risk of the virulent supervening upon the avirulent was probably not greater than the risk of the ordinary person becoming a diphtheria carrier.

The relation of the virulent and avirulent organisms awaited further investigation. It was difficult to dogmatize, and it was difficult also to draw any hard and fast line at which the exclusion of virulent carriers became justifiable or necessary. When diphtheria became prevalent certainly the virulent carrier must become an object of grave suspicion, if not of danger. Exclusion would seem also to be justifiable under certain conditions pertaining to the individual, such as the presence of large numbers of organisms in the culture, or a defective condition of throat and nose. Otherwise, in the case of mild carriers, the middle course of non-exclusion but constant supervision seemed to be possible. Unfortunately, measures of control which were adequate to the schools could not be extended outside, and the carrier might still be a source of danger in kinemas or Sunday schools. Fresh legislation might be desirable on this point, to be enforced at times of diphtheria prevalence. The treatment of the diphtheria carrier in the school had been met partly by the use of the nasal douche or suitable gargles, and partly by the provision of treatment for enlarged tonsils and adenoids. In chronic carriers the removal of tonsils and adenoids was usually effective, but there were exceptions, and he mentioned one case of a child who was a carrier for several years after enucleation of the tonsils. The evidence forthcoming, not only from the bulk of investigations into the school incidence of diphtheria of the recent two or three years, but also from special inquiry on the point in time past, went to show that the part played by the school in the spread of the disease was of quite secondary importance compared with the influence of home and out-of-school sources, which, being more beyond immediate control and supervision, were probably far more responsible for the dissemination of infection. He referred, in conclusion, to prophylaxis and the possibility of future immunization by the adoption of the Schick test on a large scale.

### TREATMENT OF FULL-TERM ECTOPIC GESTATION.

A MEETING of the Midland Obstetrical and Gynaecological Society was held at the Royal Infirmary, Leicester, on February 13th, with the President, Dr. PURSTOW, in the chair, when Mr. Cecil MARRIOTT opened a discussion on the treatment of full-term ectopic gestation.

Mr. Marriott referred to a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine in 1919, when the late Mr. Gordon Ley presented notes of 100 collected cases, from which he showed that the maternal mortality rate was high in cases of early operation, whilst there was risk of infection of the sac if the case was left for long after full term. The mortality amongst babies delivered at the time of false labour was low, and many of these babies (50 per cent.) presented various degrees of deformity. Treatment resolved itself into early or late operation. In early operation the maternal risk from haemorrhage was very great. Although in suitable cases, after primary ligation of all big vessels, the placenta and sac might be removed without severe bleeding, it was probably wiser to marsupialize the sac and leave the placenta to natural absorption. In cases where no effort was made to save the child, operation should be delayed for at least three months, by which time bleeding would be greatly lessened and the operative risks small. Mr. Marriott reported the details of a case operated on by him successfully on those lines, three months after spurious labour.

Mr. FURNEAUX JORDAN referred to one of the earliest cases successfully operated on at term by the late Professor Taylor. Mr. Jordan also reported two cases: One was operated on two years after false labour, and the sac contained only the foetal bones and some dark brown fluid; the other was seen two months after term, and presented no operative difficulties. Dr. H. T. Hicks mentioned a recent case in which he delivered a living but deformed child. Both walls of the uterus and the placenta were encountered and incised before the sac was opened. There was brisk haemorrhage, dealt with by marsupialization of the sac and plugging. In view of the formidable nature of the operation at term and the comparatively small risks of infection, Dr. Hicks strongly favoured the late operation.

Dr. T. C. CLARE mentioned a case operated on two weeks after labour, in which severe haemorrhage was encountered, although no attempt was made to separate the sac and the

placenta. Dr. C. D. LOCHRANE reported a case operated on eighteen months after labour; the placental attachment was in the Fallopian tube, and removal presented no difficulties.

#### Cases and Specimens.

Dr. H. T. Hicks showed microphotographs from a case of endometrioma of the ovary. Both ovaries on removal at operation were found to contain multiple "larry" cysts. The microphotographs showed numerous glandular spaces in the ovarian stroma lined with cylindrical epithelium. Dr. Hicks considered that the most likely explanation of these cysts was endometrial metastasis. Dr. T. C. CLARE reported three cases of adeno-myoma of the recto-vaginal septum. Dr. C. D. LOCHRANE reported (1) a case of adeno-myoma of the recto-vaginal septum showing decidual reaction during normal pregnancy; and (2) a case of adeno-myoma of the uterus in pregnancy showing decidual reaction. The cases were illustrated by lantern slides, microphotographs, and microscopic sections. Dr. Lochrane also showed a specimen of epithelioma of the vulva following leukoplakia. The case was of interest, as when first seen there was no evidence of malignant change, but when seen again after a course of x-ray treatment there was an obvious epithelioma with some glandular involvement.

### SCIATICA.

At a meeting of the Buxton Medical Research Society held at the Devonshire Hospital on February 5th Dr. J. B. BURT, in opening a discussion on sciatica, pointed out that sciatica was a symptom and not a disease. It was perhaps the most interesting condition treated at the Devonshire Hospital. He preferred dividing sciatica into trunk sciatica and root sciatica. Primary sciatica was exceedingly rare, and neuritis and neuralgia were merely stages of one condition. The commonest cause of sciatica was fibrositis of the glutei and the fascia covering this region. This was the easiest group to diagnose and to treat. On the other hand, sciatica due to fibrositis of the pyriformis was exceedingly difficult to diagnose and to treat. It might give rise to trunk or root sciatica. Pain on coughing or sneezing was suggestive of pyriformis fibrositis. In Sweden particular attention had been devoted to this cause. Gonorrhoeal fibrositis of the gluteal region must not be forgotten as a fairly common cause of sciatica. Arthritis of the hip-joint accounted for something like 10 per cent. of the cases of sciatica. Sacro-iliac disease was not so common a cause of sciatica as it seemed at first sight. Acute tenderness along the ridge of the sacro-iliac joint occurred in many cases of sciatica where there was no disease of the joint. Inflammation of the bursae around the hip-joint might give rise to very severe sciatica.

Root-sciatica was distinguishable from trunk sciatica by (a) broad bands of pain extending from the gluteal region along the back and side of the thigh, (b) tenderness of the psoas muscle, (c) wasting of the leg muscles and glutei, and (d) sometimes by the attitude of the patient in walking. Syphilis was an important cause of this condition; it generally gave rise to bilateral sciatica.

Dr. Burt, in emphasizing the importance of diagnosing adhesions, said that the following three points were suggestive of adhesions: (1) a long-continued dull pain extending over a period of months; (2) the patient is ailing and unrelieved by rest; (3) the patient gets out of bed; (4) the patient sits with his back against the wall with his legs extended straight in front of him. With a sciatic adhesion it was practically impossible to touch the floor with the back of the knee. If the results obtained by other physicians corresponded with his, this test should prove of great clinical value.

### X RAYS IN GYNAECOLOGY.

At a meeting of the London Association of the Medical Women's Federation held at the Elizabeth Garrett Anderson Hospital on February 12th, with Mrs. FLEMING, M.D., Vice-President, in the chair, a paper was read by the President, Miss LUCIA MARTINDALE, M.D., entitled "Modern technique in the x-ray treatment of gynaecological conditions."

Dr. Martindale divided her subject-matter into two parts: First, the treatment of cases by the Freiburg method between 1914 and 1920. During this period Dr. Martindale had treated a large number of cases of uterine fibroids with intensive x-ray

At a meeting of the West Kent Medico-Chirurgical Society, held at the Miller General Hospital, Greenwich, on February 9th, with Dr. W. H. PAYNE in the chair, Dr. JOHN PARKINSON, physician in charge of the Cardiological department, London Hospital, delivered an address on palpitation. He defined palpitation as consciousness of the heart beat—a subjective and sensory phenomenon, to be distinguished from tachycardia, for it was possible to have palpitation with a normal rate. The carditis was caused by afferent impulses through the vagus to the brain, and also by the heart beating against a too sensitive chest wall, and was uncommon in children or old people, but common at puberty and the menopause. The patient should be questioned about the duration and exciting cause. Palpitation at bedtime was frequently due to extra-systoles. The site might be the heart, neck, ears, and aorta. The attacks were often circumscribed. Dyspeptics were subject to palpitation; fear and emotional states (such as that due to speech making) were causes. Palpitation was prone to occur in highly strung, easily excited persons, and in those too concerned about themselves; also in thyroid cases. A loud first sound was frequent, but not a sign of disease. The apex beat was diffuse. Alcohol, tea, tobacco, worry, grief, and exercise were causes of tachycardia, which should be treated by bromides—not brandy. Persistent simple tachycardia was caused by hyperthyroidism, also by tuberculosis of the lungs and anaemia. In paroxysmal tachycardia the rate was from 140 to 240, and irregularity was always present in auricular fibrillation.

## Reviews.

### THE AUTONOMIC NERVOUS SYSTEM IN DISEASE.

*The Sympathetic Nervous System in Disease*,<sup>1</sup> by Dr. LANGDON BROWN, now in its second edition, is based on the Croonian lectures at the Royal College of Physicians of London for 1918, with the almost identical title, "The rôle of the sympathetic nervous system in disease"; it is a clear and attractively written account of a subject not only inherently difficult, but prone to be obscured by unproved hypotheses. With the wise moderation of a general physician, Dr. Langdon Brown has so happily combined the results of wide experience, reading, and a physiologist's education that it is not surprising that a second edition has become necessary. In the first chapter, dealing with the plan of the autonomic nervous system, a well deserved tribute is paid to the pioneer work of the author's teachers, Professor J. N. Langley and the late Dr. W. H. Gaskell; our knowledge of the sympathetic nervous system in the pre-Gaskell era is compared to that of the circulation before Harvey. His consideration of the pharmacological action of certain drugs on the autonomic nervous system is useful not only in facilitating comprehension of its make-up, but in estimating the value of the conception of vagotonia and sympathicotonia due to Eppinger and Hess; in a later chapter devoted to vagotonia critical examination brings out the grave difficulties in accepting this ingenious hypothesis in its entirety, and shows that the case has been much overstated, though it contains a germ of underlying truth which deserves further investigation.

Though he does not profess to deal exhaustively with the reaction of the autonomic nervous system to disease Dr. Langdon Brown covers a wide field in the successive chapters on its relation to the endocrine glands, glycosuria, diseases of digestion, and to circulatory disorders. He argues that no theory of diabetes is adequate which leaves the sympathetic nervous system out of account, and that, if Graves's disease is a state of continuous fear, diabetes is a state of continuous mobilization of sugar, and that either of these may be due to dissociated action of the sympathetic nervous system.

After a discussion of the innervation of the alimentary canal and the work of Gaskell, Hurst, Keith, and others, its motor disturbances are summed up as (1) irregular and exaggerated contractions due to irritation of the parasympathetic, when in the region of the vagus producing colic, when in the pelvic area tenesmus; and (2) tonic spasm and atony, which are both due to the sympathetic, spasm depending on constriction of sphincters, atony, as in gastric dilatation, on inhibition of normal movements.

The chapter dealing with diseases of the circulation contains close reasoning on the relations of intracranial pressure and arterial blood pressure, and then shows the vicious circle that arises in cerebral haemorrhage and how vena-section acts adversely; similar points in practical treatment are explained in cardiac and pulmonary diseases, and recent advances in our knowledge of shock are summarized. In fact, this is one of the most interesting chapters in a book on which the author may justly be congratulated.

### FUNCTIONAL EXAMINATION OF THE LUNGS.

A short book (*Examen fonctionnel du Poumon*), beautifully printed and illustrated, and moderate in price, has just been published by Professor ACHARD and Dr. LÉON BINET of Paris. In the preface the authors rightly point to the great advances which have been made recently in the functional interpretation of disease and the application of experimental methods in elucidating functional failures. We therefore turned with much interest to their book.

The first part deals with the mechanical aspects of breathing. Graphic and other methods are described for recording and measuring the movements of the chest, the volume of air breathed, and the vital capacity. There are also sections on the x-ray observation of the diaphragm and on the time during which the breath can be held. The abnormalities revealed in disease by these methods are at the same time referred to. There is, however, hardly any reference either

to the functional significance of the physiological causes of these abnormalities; nor are the different types of increased, diminished, or otherwise abnormal breathing clearly described. We expected to find the missing links in the second part, which deals with the chemical phenomena of breathing. This part begins with methods for determining respiratory exchange, and proceeds to discuss basal metabolism and diseases in which it is abnormal. There is also an interesting section on the influence of ingestion of sugar on the excretion of CO<sub>2</sub> in normal persons, in diabetes, and in other diseases. At the end there is a description of a not very accurate method of determining alveolar CO<sub>2</sub> pressure, and a short reference to the fall of alveolar CO<sub>2</sub> pressure in diabetes. The physiological significance of this fall is hardly even hinted at; and indeed one searches in vain in the second part for any chemical or other connecting link with the abnormal breathing referred to in the first part.

The truth is that the book practically ignores the advances during the last twenty years in the physiology of breathing and of the blood gases. There is not a word about the significance of changes in the gas pressures and hydrogen ion concentration of the arterial and capillary blood, or of variations in the pressure of CO<sub>2</sub> in the lung alveoli; nor about functional nervous abnormalities of breathing. Without the connecting links supplied by physiological and clinical investigation mere descriptions of methods and symptoms are of only limited use. The authors have unfortunately missed the opportunity of writing a most instructive book, such as we might have hoped for from countrymen of Paul Bert.

### THE THEORY OF EMULSIONS.

*The Theory of Emulsions and Emulsification*,<sup>2</sup> by Dr. W. CLAYTON, is one of the series of "Textbooks of Chemical Research and Engineering" edited by Mr. W. P. Dreaper.

Professor Donnan has written a foreword, in which he points out the manifold directions in which the subject of emulsions is interesting. Milk, butter, margarine, the emulsions and ointments of pharmacy, the coal-tar disinfectants, rubber latex, and emulsified lubricants are a few examples of common and important emulsions.

Dr. Clayton gives a very clear account of the laws governing the behaviour of emulsions, and the book concludes with a bibliography of about 200 references. So far as we are aware, no previous monograph upon emulsions has been compiled. Those desiring information on this subject have accordingly had to try and find it in the textbooks of colloidal chemistry; in most of them the subject is dealt with in a very piecemeal fashion.

Considerable attention is paid to the technical problems involved, and the book should be of great value to the pharmacist who desires to learn the laws which govern the formation and stability of emulsions. It will be of great theoretical interest to the physiologist, for the recent work by Clowes and others upon emulsions of oil and water is discussed fully. Clowes showed that an emulsion of oil drops in water could be changed to an emulsion of water drops in oil by the addition of some electrolytes, and that the change was prevented by other electrolytes. This observation is of very great concern to physiologists, because living protoplasm is believed to consist of an emulsion of lipoids in proteins, and Clowes's work suggests a means by which the addition of electrolytes can alter the physical state of the surface membrane of cells and rapidly change their permeability. This is only one of the many interesting problems dealt with in the book, which will be found of value by a large variety of readers, dealing as it does with problems that range from the best methods of producing homogenized milk for ice cream manufacture to the methods employed for separating water from crude oil at oil wells.

### DISEASES OF THE THYROID GLAND.

Dr. ARTHUR HERTZLER's *Diseases of the Thyroid Gland*<sup>3</sup> is a book of unusual interest in that the information contained therein is the result of years of experience of the treatment of these diseases in a small country hospital. After mentioning the disadvantages the author points out the advantages to be derived from this method of study—for instance, the isolation

<sup>2</sup> *Examen fonctionnel du Poumon*. Par Ch. Achard et Léon Binet. Paris: Masson et Cie. 1922. (Med. 8vo, pp. 151; 66 figures. Fr. 12 net.)

<sup>3</sup> *The Theory of Emulsions and Emulsification*. By W. Clayton, D.Sc., F.I.C. Textbooks of Chemical Research and Engineering. London: J. and A. Churchill. 1923. (8vo, 160 pp. 10s. 6s. net.)

<sup>4</sup> *Diseases of the Thyroid*. By Arthur Hertzler. London: H. Kimpton. 1922. (8vo, 128 pp. 10s. 6s. net.)

gives the investigators more freedom to follow their own ideas, uninfluenced by the opinion of associates; the small country hospital, drawing its patients from a stable population in the immediate community, is better able to study the end-results, and it is only by frequent re-examination of the patient that an accurate idea of the course of the disease can be obtained. As the result of his studies the author is convinced that the activity of the interstitial cells is associated with a definite clinical type of thyroid intoxication; hence the publication of this monograph.

The first and second chapters are concerned with the etiology and pathogenesis of goitre, with the pathological conditions of other organs, and with the normal and pathological anatomy of the thyroid gland. The etiology is discussed in its relation to such factors as age, sex, genital functions and disturbances, pelvic conditions, heredity, endemology, infection, previous and associated diseases, and the neurogenic and thyrogenic theories. In the chapter on symptomatology he asserts that there is no such thing as a simple goitre, holding that goitres are either toxic or non-toxic, and the physician or surgeon must consider the so-called simple goitre as one not yet toxic, and treat the patient accordingly, otherwise his treatment may quickly convert it into a toxic one. He is also of opinion that in every case of goitre, whether toxic or not, there is either enlargement or anatomical change in the gland, and that those who hold the opposite view have yet to demonstrate the existence of a normal gland in patients who have suffered during their life from any form of thyroid disease. The chapters on diagnosis and prognosis deal with the adolescent goitres, the simple—or non-toxic—colloid goitres, secondary toxicity and malignant degeneration in such, together with affections of other organs, the primary toxic goitres—exophthalmic and non-exophthalmic—secondary toxic goitres, and atypical and hyperacute forms of these. His remarks on the interstitial type (*formes frustes*) (first described by Charcot and G. Marie) are interesting, and ought to be extremely helpful. His opinion of the Goelsch test is that it is only of relative value, because many patients not thyrotoxic are susceptible to adrenaline, while some with toxic goitres are not susceptible. When the diagnosis is evident from other signs and symptoms the test should not be performed, as its use often frightens the patient, owing to the exacerbation it causes when the larger amount is injected, while the smaller injection gives inconstant results. It is chiefly useful in border-line cases; in those that appear to be simply nervous a positive reaction may be given years before any other evidence of goitre appears. The author is doubtful also of the value of the basal metabolic rate test, and thinks that it is only of use in inverse ratio to the clinical experience of the surgeon. An interesting chapter on hospital management of goitre cases has been contributed by Dr. Victor Chesky, in which pre-operative and post-operative treatment and complications are dealt with. The rest of the book is concerned with treatment, general and operative, with descriptions and illustrations of the various operations performed on the thyroid gland.

This is a well written book, the references to current and past literature are numerous, the illustrations are excellent, and the author's opinions are carefully thought out.

### THE BIOLOGY OF DEATH.

It is the common fate of those nominated to lecture upon famous foundations in this country to find that neither the size nor the enthusiasm of the audience is commensurate with the dignity of the lectureship. The lecture theatres even of the Royal Society or the London College of Physicians are rarely packed to overflowing when the Croonian discourses are pronounced. Possibly the English nation has been over-lectured; or, again, it may be that the correlation between scientific eminence and elocutionary power is small. In America, we believe, the lecture-loving public is much larger. If Professor RAYMOND PEARL had a large audience for his Lowell lectures<sup>5</sup> in 1920, he must have convinced his hearers that they were wiser than the inert English, for his course was wonderfully stimulating.

Professor Pearl begins by defining his problem; he has no difficulty in showing that natural death is not the inevitable penalty of life—that, on the contrary, it occurs only in metazoan animals as a normal event, that even highly specialized

cells are potentially immortal. He shows no mercy either to Weismann's theory that death is an advantageous adaptation preserved by natural selection; which, as he says, enjoyed a vogue "when the post-Darwinian attempt to settle the problems of evolution by sheer dialectic was at the zenith of its popularity," or to Metchnikoff's hypothesis. The chief difficulty with Metchnikoff's theory is, he says, "that it is demonstrably not true—either particularly in the case of man, where it can easily be shown that many statistically important causes of death cannot possibly be accounted for under it, or generally in the animal kingdom—because a number of cases are known where a metazoan form can be successfully made to lead a completely aseptic life, and still death occurs at about the usual time."

Why do metazoans die, then? Essentially Professor Pearl's answer is the same as that great pathologist H. G. Sutton's definition of disease—absence of rhythm. The body is not made like the wonderful "one-hoss shay"; the cellular systems fall out of balance, the environmental conditions which experiment shows to be necessary for cellular immortality are not maintained, or, as in malignant disease, there may be an outbreak of cellular bolshevism which destroys the commonwealth. What is the best way to live as long as possible? The best way of all is to be very careful in choosing one's ancestors. An analysis of Bell's statistics of the Hyde family and of the opinions of physicians on the preventability of various diseases leads Professor Pearl to conclude that, "if all the deaths which reason will justify one in supposing preventable on the basis of what is now known were prevented in fact, the resulting increase in expectation of life falls seven years short of what might reasonably be expected to follow the selection of only one generation of ancestry (the parental) for longevity." Another factor is the rate at which one lives. The world has long been of this opinion, which has been expressed by the sages of all times and in the adages of most nations. The additional support afforded by Slonaker's experiments upon four albino rats made to run a prodigious number of miles and dying at an average age of 29.5 months, while three control rats living a life of *otium cum dignitate* attained an average of 40.3 months, is meagre. This sort of experiment reminds us of the sage who could—

"Resolve by sines and tangents straight,  
If bread or butter wanted weight;  
And wisely tell what hour o' th' day  
The clock does strike, by Algebra."

Is the greatly higher rate of mortality in later adult life of our industrial districts, compared with our agricultural districts, more likely to be a function of a higher rate of transformation of mere physical energy or of a much more subtle thing—what the public calls "nervous strain"? The man in the street will certainly say that the latter is the right answer. It is necessary to try to think clearly what precise meaning can be attached to the phrase "nervous strain" and then to investigate its social and economic correlates. For once we disagree with Professor Pearl, and do not think that, "as in so many other cases, the experimental method is likely to shed far more critical light on this problem than is the purely statistical method dealing with human data. There are too many factors in the latter material that cannot be controlled." They cannot be controlled, but perhaps they can be observed and measured. There are many other points in Professor Pearl's lectures, such as his extremely interesting study of longevity in flies, well worthy of examination. The first cross of a biologist and statistician is a very attractive hybrid.

### MALIGNANT DISEASE.

In an interesting and well expressed essay on the origin of cancers and other tumours M. JOSEPH STÉFANI,<sup>6</sup> a surgeon at Nice, first reviews the existing opinions about the etiology and nature of malignant new growths and therein of course touches on many points that have aroused discussion. In opposition to the statement that cancer is contagious it has been objected that operating surgeons seldom suffer from it, but the author denies this, believing that this occurrence is common. Cancer houses are discussed, and here, as elsewhere, many authorities are quoted—for example, Gaylord and Clowes's observations on cancer cages. With regard to heredity it is considered probable that the cases which have been interpreted in this way are in reality due to familial

<sup>5</sup> *The Biology of Death*. By Raymond Pearl. Monographs on Experimental Biology. Philadelphia and London: J. B. Lippincott Co., 1923. (Post 8vo. pp. 275; 64 figures. 10s. 6d. net.)

<sup>6</sup> *Essai sur l'origine des cancers et tumeurs*. By Dr. Joseph Stéfani. Paris: A. Maloine et Fils. 1922. (Imp. 16mo. pp. 103. Fr. 10)

infection. Whilst believing that malignant disease is due to infection the author does not accept any of the current parasitic hypotheses. In the second part of his essay he elaborates his own theory to the effect that there is a special form of infection at work—namely, a process of conjugation between the cells of the host and unicellular organisms, probably protozoal, which gives rise to unicellular hybrids, the tumour cells.

*Cancer: its Cause, Treatment, and Prevention* is a reprint, with some additions, of a series of addresses published between 1902 and 1910 by Dr. A. T. BRAND,<sup>7</sup> in which he insists on the infective origin of cancer, its exogenous and specific nature, and the presence of a parasite—whether protozoal or bacterial, though he is in favour of a facultative aerobic bacterium—in the cells. The only reliable prophylactic against cancer is held to be cleanliness in its widest sense, including cremation of its victims and destruction by fire of all soiled dressings and discharges from cancerous patients. After advocating free operative removal of the growth, Dr. Brand pleads for research for a specific parasiticide.

In the tenth number of the Harvard Health Talks, delivered as a popular Sunday afternoon lecture at the Harvard Medical School, on *New Growths and Cancer*, by Professor S. B. WOLBACH,<sup>8</sup> the present state of our knowledge is clearly and simply set forth with suggestions for prevention and treatment. As statements meeting with general scientific approval, he mentions the non-hereditary and non-infectious nature of cancer, so that it cannot be transmitted from person to person. On the question of the alleged increase of cancer, the dictum of Professor Willcox of Princeton that it is probable, although far from certain, that the cancer mortality is not increasing, is quoted with approval. This common-sense lecture concludes with some wise advice on the care that should be exercised in choosing a doctor, and points out that the more rapidly the public learns to be discriminating in its choice of medical men the more rapidly will the standards in the practice of medicine become elevated.

The Provincial Board of Health, Ontario, has issued two pamphlets—*What We Know about Cancer, a Handbook for the Medical Profession*, and *What Everyone Should Know about Cancer, a Handbook for the Lay Reader*;<sup>9</sup> both of these were prepared by a special committee of the American Society for the Control of Cancer, and have been republished with the consent of the society. The increased incidence of malignant disease throughout the world is accepted; in Ontario during the last decade the cancer mortality has risen from 66 to 77 per 100,000, while that from tuberculosis has diminished from 102 to 78 per 100,000. Recent investigations show that malignant disease is rare among the Indians in Canada; although white races are considered to be more liable to cancer than North American Indians and Orientals, cancer of the uterus in America is apparently more frequent in negro than in white women. These two useful pamphlets are full of common sense and good advice.

In *Le cancer et son traitement médical rationnel*<sup>10</sup> Dr. E. BARONAKI argues that malignant disease is a local manifestation of a general dyscrasia resulting from functional disorders of the endocrine glands, which in its turn is due to age, hereditary influences, infections, especially enteric fever and syphilis, mental shocks, and to excess of calcium in drinking water. The blood shows alterations in the organic ferments, in the plasma, which is stated to be almost always acid and deficient in salts, especially of calcium. His treatment consists in intramuscular injections of neoplastin—a solution of salts of calcium, potassium, sodium, magnesium—and phosphorus, for twenty days, and in addition cachets of cholestérine, lecithine, and haemoglobin, and the administration of the liquid extracts of thyroid, the adrenal, liver, and spleen. In doubtful cases eventually proved to be free from cancer the injections

of neoplastin cause digestive disturbance, but otherwise the treatment is stated to be harmless, and thus may serve as a means of diagnosis. In early cases of malignant disease not involving any vital part a cure is claimed in 80 per cent.; in recurrences on the surface of the body, especially of the breast, without visceral metastases, cure or a stationary condition for some years is said to follow in 70 per cent.; in widespread visceral malignant growths no curative action is suggested. This unconvincing and insufficiently proved argument closes with the record of twenty cases.

#### DEAN INGE'S ESSAYS.

THE second series of *Outspoken Essays*,<sup>11</sup> by the Dean of St. Paul's, is a most attractive collection of essays on the problems of this troubled age. More than half of the book has not been published elsewhere. The first article, *Confessio fidei*, explains what and why the author, who would describe himself as a Christian Platonist, believes. The Hibbert Lectures, delivered at Oxford in 1920, on *The State, Visible and Invisible*, the Romanes Lecture for 1920 on *The Idea of Progress*, and the Rede Lecture for 1922 on *The Victorian Age*, contain much interesting matter.

Both in the Hibbert lectures and in *The Victorian Age* the principle that all human movements tend to provoke violent reactions, and that every idea or institution passes on to its opposite, is regarded as the keynote of history. The nineteenth century was the most wonderful century in human history, and the Victorian age the culminating point of our prosperity; and as an antidote to the evil fashion of disparaging the great Victorians the Dean recommends a comparison of their portraits with those of the present-day favourites. In *The White Man and his Rivals* it is argued that the peril from the coloured races, which before the war loomed in the distance, is now of immediate urgency, and that the exhausted and debt-crippled white nations will be defeated in the coming economic competition. The article entitled "*The Dilemma of Civilization*" reviews the contents of two recent books on scientific sociology by Müller Lyer and Austin Freeman, and discusses the possible escape from the conditions brought about by machinery. The concluding essay, on *Eugenics*, insists on the necessity of counteracting racial deterioration by rational selection. These essays make a strong appeal to all thoughtful men, and are clearly and convincingly written.

#### NOTES ON BOOKS.

THE third edition of Sir JOHN MCFADYEAN'S *Anatomy of the Horse*<sup>12</sup> will be welcomed by veterinary students, for it has been the standard British textbook for many years. The whole of the text has been carefully revised, and the name of the author is sufficient guarantee that it has been brought up to date, especially in regard to nomenclature, about which there are still some differences; it is necessary for the student to be aware of these when about to present himself before a board of examiners in anatomy. The system Sir John McFadyean employs is based on the principle of naming each object after the homologous object in human anatomy; at the beginning of the book is a very well arranged table showing the synonyms of the muscles; in this the first column, giving the author's nomenclature, is followed by that of Percival, Chauveau, and Legh. In the earlier chapters the dissection of the limbs, of the back and thorax, of the head and neck, and of the eyeball and ear, are dealt with in order, and then that of the various important internal organs of the thorax and abdomen. Each is lucidly described and excellently illustrated, the whole being typical, as in previous editions, of the thoroughness and care which have been bestowed upon the book. The book has long been prized, and will long be prized, by the veterinary student, and should find a place on the bookshelf of every veterinary practitioner who wishes to keep himself abreast of the times.

The third number of the fourth volume of the *Annals of Medical History*<sup>13</sup> has two portraits of Louis Pasteur—one on the cover, and a frontispiece, the familiar representation of

<sup>7</sup> *Cancer: its Cause, Treatment, and Prevention*. By Alex. Theodore Brand, M.D., C.M., V.D. London: John Bale, Sons, and Danielsson, Ltd. 1922. (Post 8vo, pp. viii+120. 8s. 6d. net.)

<sup>8</sup> *New Growths and Cancer*. By Simeon Burt Wolbach, Shattuck Professor of Pathological Anatomy in Harvard University. Harvard Health Talks, No. 10. Cambridge, Mass.: Harvard University Press; London, Humphrey Milford, 1922. (Fcap 8vo, pp. 55; 2 plates. 4s. 6d.)

<sup>9</sup> *What We Know about Cancer; a Handbook for the Medical Profession*. 1922. (Pp. 58.) *What Everyone Should Know about Cancer; a Handbook for the Lay Reader*. 1922. (Pp. 26.) Published by the Provincial Board of Health, Ontario.

<sup>10</sup> *Le cancer et son traitement médical rationnel*. Par Ed. Baronaki. Chirurgien honoraire de l'Hôpital-Dieu de Blois. Paris: A. Maloine et Fils. 1922. (Cr. 8vo, pp. xv+101. Fr. f.)

<sup>11</sup> *Outspoken Essays*. By William Ralph Inge, C.V.O., D.D., F.B.A., Dean of St. Paul's. Second Series. London: Longmans, Green and Co. 1922. (Cr. 8vo, pp. vii+275. 6s. net.)

<sup>12</sup> *The Anatomy of the Horse: a Dissection Guide*. By Sir John McFadyean, M.B., C.M., B.Sc., M.R.C.V.S. Third edition. Edinburgh and London: W. and A. K. Johnston, Ltd. 1922. (Demy 8vo, pp. xx+383; 54 figures, 48 plates. 3s. net.)

<sup>13</sup> *Annals of Medical History*. Vol. iv, No. 3, September, 1922. Serial Number 15. Edited by Francis R. Packard, M.D. New York: Published quarterly by Paul B. Hoeber. (Med. 4to, pp. 215-322. Yearly subscription 6 dollars; single numbers 2.50 dollars.)

him in his laboratory. The editor, Dr. FRANCIS R. PACKARD, continues his interesting account of Guy Patin and the medical profession in Paris in the seventeenth century. In the next article—on Robert Talbor, Madame de Sévigné, and the introduction of cinchona, an episode illustrating the influence of women in medicine—Dr. George Dock of St. Louis describes how he picked up in Shaftesbury Avenue, for a trifling sum, Robert Talbor's *Pyretologia*, of which the only other copy known to him is in the British Museum; Talbor advocated the use of cinchona in a work savouring strongly of the charlatan, but numerous extracts from Madame de Sévigné's letters breathe her belief in him. Dr. Robert Wilson discusses the origin and symbolism of the caduceus, and concludes that, whether the caduceus in its present form originated as an Egyptian or as an Assyrian device, its symbolism dates back to predynastic Egypt. The Hon. W. R. Riddell, President of the Canadian National Council for Combating Venereal Disease, gives a sketch of Dr. George Cheyne and "the English malady," in which he remarks that though usually a disease named after a nation is an expression of enmity, as is shown by the nomenclature of venereal disease, the condition was different as regards the "English malady," a combination of neurasthenia, melancholy, and dyspepsia, described by Cheyne. In a well illustrated account of the early history of anatomy in the United States Dr. E. B. Krumpholtz shows that Thomas Cadwalader of Philadelphia was the first to initiate the scientific study of anatomy, and that the first course of lectures and demonstrations was given by William Shippen junior in 1765, when, together with John Morgan, he founded the medical department of the University of Pennsylvania in Philadelphia. Dr. Burton Chance writes on some English worthies of science of interest to ophthalmologists—namely, Sir Isaac Newton, W. H. Wollaston, J. Dalton, and Thomas Young, "Phenomenon Young," as he was called at Cambridge.

The second volume of the Oxford Chapters in the History of Science, edited by Dr. CHARLES SINGER, is a translation of Professor Heiberg's *Naturwissenschaften, Mathematik und Medizin im Klassischen Altertum*. Within the compass of 105 pages the author has contrived to give a remarkable amount of information in a readable form. The difficult task of giving a non-technical account of Greek mathematics has been skilfully performed, while the account of the medical writers, if in places somewhat amateurish, is lucid and interesting.

In his book *The Problem of Population* Mr. HAROLD COX discusses in an orderly way the facts of the population problem and the ethics of birth control. The author does not, we think, bring forward any statistical or economic evidence which has not long been familiar to all serious students of the subject, but he possesses one great advantage over many other writers. He has thorough command of a clear prose style, rarely diverges from argument into rhetoric, and deserves the compliment of a comparison with Malthus.

<sup>2</sup> *The Problem of Population*. By Harold Cox. London: J. Cape. 1923. (Cr. 8vo, pp. 193. 6s. net.)

## MEDICINAL AND DIETETIC PREPARATIONS.

### "Secwa."

SECWA is a dry powder product introduced by Trufood Ltd. (The Creameries, Wrenbury, Cheshire) for the preparation of sweet whey. The manufacturers claim that it contains all the components of ordinary fresh milk, except the casein and fat, and of course the water. A sample has been submitted to analysis, and is found to consist only of the dried contents of milk whey. It contains no starch or other matter foreign to the composition of milk, and it is free from boric acid and milk preservative.

The following is the composition shown by our analysis:

Protein	...	...	...	19.33 per cent.
Lactose	...	...	...	67.70 "
Mineral matters (ash)	...	...	...	9.02 "
Fat	...	...	...	0.66 "
Moisture	...	...	...	3.25 "

The characters of the sample show that the constituents have suffered no injury or alteration in nature through the process of desiccation. There is no sign of the change of colour which articles of this nature readily undergo if unduly heated, and the lactalbumin (whey protein) is perfectly soluble.

## SLEEPING SICKNESS:

### SOME NEW OBSERVATIONS ON ITS TRANSMISSION AND PREVENTION.

WHEN the discovery, in 1908-10, of scattered cases of human trypanosomiasis in North-East Rhodesia and Nyasaland led to the appointment of commissions for their investigation (the Royal Society's Commission under Sir David Bruce in Nyasaland and Dr. Kinghorn and Dr. Warrington Yorke in Rhodesia) it was found that, in its morphology, its action on animals, and its reactions to culture and serums, the new trypanosome, *T. rhodesiense* of man, was indistinguishable from a trypanosome which infested the game of the same regions. So close was the resemblance that the investigators felt that they could come to no other conclusion but that the two trypanosomes were specifically identical, and that the big game was the main or only reservoir for Nyasaland sleeping sickness. On this conclusion was based a practical recommendation—namely, that an experiment in game destruction should be made under scientific control. An area was to be selected and, after certain preliminary statistical investigations, the game in it was to be completely eradicated, and the entry into it of game from other areas prevented by a suitable barrier. In two or three years the population, the live-stock, and the tsetse fly were to be examined again. Even if the fly had not then disappeared owing to the absence of the game it might at least be found that it had become non-infective. In either event the policy would then be to kill and drive away game in the neighbourhood of human habitations and roads.

Both the experiment and the policy were recommended by the Inter-Departmental Committee, which reported in May, 1914, but the validity of the conclusion which had first prompted these suggestions had already been seriously questioned. It was pointed out that in vast areas of Africa *Glossina morsitans*, human beings, game, and *T. brucei* were present together, and that the incidence of Nyasaland sleeping sickness would be far higher were this trypanosome pathogenic to man. Taute even inoculated himself repeatedly, and, at a later date, he and Huber inoculated themselves and 129 natives, many of them debilitated, with the game trypanosome, without obtaining a single positive result.

Duke, however, in 1919, published in respect of the Uganda disease the suggestion that, man being highly resistant to trypanosome infection (a criticism of Taute's experiments which had already been made), human trypanosomiasis in epidemic form can only be brought about, and is brought about, by repeated transmissions of the trypanosome from man to man direct; in the laboratory it is often possible by this method to render virulent for a particular species of animal a strain of trypanosome to which it was previously refractory, and Duke suggested that this mechanical transmission was effected in nature by *G. palpalis* itself, and that the crowded canoes, accompanied by tsetse flies, of the Victoria Nyanza provided the ideal condition. If this were applicable to *G. morsitans* also and the scattered cases of Nyasaland, it followed that Taute's experiment had not gone far enough, and that *T. brucei*, transmitted directly from man to man, might after all be capable of giving rise to *T. rhodesiense*.

The next light on the problem has come from an outbreak of sleeping sickness of the *rhodesiense* type in the country south of the Speke Gulf, in the Mwanza District of Tanganyika Territory, about six and a half degrees farther north than the most northerly cases of the disease previously recorded, though we now have news from Dr. Archibald of a discovery of *rhodesiense* sleeping sickness in the Sudan. The Mwanza outbreak, which began probably about 1917 and comprised a few hundred cases, is interesting for at least two reasons. In the first place, the disease prevailed as an epidemic, a new feature in the Nyasaland type; and secondly, it was carried, not by *G. morsitans*, but by a new fly of the same group that has been described by Major Austen as *G. swynnertoni*. The outbreak was discovered by Dr. G. Maclean, of the Medical Department of Tanganyika Territory, and has been investigated in turn by Mr. Swynnerton and by Dr. Duke. Each has now published his account of it.

Swynnerton, studying the outbreak from its entomological aspects, has published his account of it in the *Entomological Aspects of an Outbreak of Sleeping Sickness near Mwanza, Tanganyika Territory*, by C. F. M. Swynnerton, F.R.S., F.E.S., *Bull. Ent. Res.*, vol. xiii, Pt. 3, pp. 317-350; and "An Enquiry into an Outbreak of Human Trypanosomiasis in a *Glossina morsitans* Belt to the East of Mwanza, Tanganyika Territory," by H. Lyndhurst-Duke, M.D., *Bacteriologist, Uganda Protectorate, Proc. Roy. Soc. Ser. B*, vol. 24, No. B. 660, January 4th, 1923.

side, found that, within the sleeping sickness area, the tsetse flies, which were very numerous, were exceptionally voracious in relation to man and in general presented the high proportion of females that has come to be recognized as the sign of a scarcity of food animals. Investigation showed that something not unlike the proposed experiment in game destruction had here been produced by natural causes. Tsetse flies do not frequent closely cultivated areas but live and breed in natural woodland. A corner of the woodland in this fly belt had been cut off from the rest by a discontinuous strip of native settlement. This strip acted as a partial barrier against the game animals and to an appreciable extent hindered the replenishment of the game in the enclosed section. The game inside became much reduced, though by no means exterminated, and the reduction was particularly marked at and after the time the epidemic probably began, because the normal activities of a large contiguous hunting population were then reinforced by the passage of troops and the incentive to wholesale killing that was furnished by a severe famine. In addition two important factors might be thought of as tending to diminish natural resistance: famine and influenza swept the land in the train of the military operations in Mwanza in 1917, and much ankylostomiasis was present in the population.

Sleeping sickness was definitely present in the area at the beginning of 1918. It seems to have started in the neighbourhood of a place called Igombe and to have spread with much regularity from village to village in different directions until it reached the cleared and settled "barrier." Areas of more open woodland with fewer tsetse flies, the barrier itself, and the coming into contact with a larger game population are three explanations offered by Swynnerton for an apparent check to the epidemic at this stage. He found it easy to trace a sequence between any case and preceding cases, and in this is strongly confirmed by Duke. Thus a woman sick with *malati* came from Ndagalo and stayed at two villages near Nyasambi, at the second of which she died. Shortly afterwards cases occurred at each village, and the people from neighbouring villages who regularly visited and sat with the sick and attended the mourning fell ill in their own villages, where further cases then occurred. One case taken to a clean village to be nursed introduced the disease there, and a "beer drink" at that village, where there were many tsetse flies, passed the disease on further. This was the story everywhere; going to see the sick and taking the sick in were, Swynnerton states, the commonest sources of infection recognized by the natives.

Duke believes that the outbreak originated through the development from the game trypanosome of a strain pathogenic to man, as a result of free direct transmission following game destruction and the consequent concentration of the fly on man. Swynnerton presents two alternative explanations—the first is the same as Duke's, the other the possibility of the disease having arisen through the introduction of an infected human being. In favour of the second alternative he points to the subsequent course of the outbreak, to the general analogy with Uganda sleeping sickness, and to the fact that in this very district the Germans captured Belgian native soldiers infected with trypanosomiasis, one of whom stated that he had been treated for it already in his own country. Each explanation involves what is at present a hypothesis: the first that *T. rhodesiense* can arise from *T. brucei*, and, in addition, that this happened here; the second that *T. rhodesiense*, already differentiated as a human strain, either came from far south or exists undiscovered in the little investigated Congo.

After describing the habits of the natives and the conditions in the villages, Swynnerton concludes that the tsetse flies had abundant opportunity of biting the sick, and that any infected person may be an important reservoir of the disease; he points out also that factors favouring direct transmission by this fly of the *morsitans* group were present. Duke adduces observations and arguments in favour of the probability that direct transmission was present to the exclusion of cyclical transmission. Both agree that the game, far from being a menace, is a valuable buffer between man and the fly. They hold that reduction of the game must lead to greater concentration of the tsetse on man, and consider that this factor probably contributed to the production of the epidemic. It is reasonable to suppose that the greater the number of tsetse flies driven to feed on man the more easy and frequent will be the infections and the greater also the likelihood of direct transmission such as might either render a game trypanosome pathogenic for man or help a human trypanosome to overcome man's normal resist-

ance. Swynnerton points out that in Northern Rhodesia in 1911-13 famine, with game present in abundance and with sporadic human trypanosomiasis existing, failed to produce an epidemic. He regards famine and game destruction as likely to be the most dangerous combination, but believes the latter to be highly dangerous in itself, if human infection exists; he cites instances recorded by others which suggest that sleeping sickness in the epidemic form tends to accompany a scarcity of game. This is a point worthy of further study. Meanwhile it will be well to walk warily in the matter of eradicating the game from the neighbourhood of human habitations in tsetse-infected bush.

The connexion traced by Duke between ankylostomiasis and sleeping sickness in the Mwanza outbreak seems likely to be important, and his suggestion as to its further investigation should be followed up; the rarity of the disease in children is of interest, and bears out Ingram's conclusion that "age, sex, and race incidence in human trypanosomiasis vary directly with the extent to which the individual is exposed to the bite of infective tsetse flies"; the fact that visits to the sick people in infected "bush villages" resulted in many infections, even in villages outside the tsetse forest, is also worthy of note. In a specially infested small bush village Swynnerton captured about 200 tsetse flies, and noted that the inhabitants were attended by them in all their occupations.

The chief significance of these two investigations is the evidence they afford that under the conditions described man was the important reservoir. While it seems possible that *T. brucei* is capable of conversion into a strain pathogenic to man, it seems unlikely that this often happens in nature. On the other hand, we have to remember that any of the four or five hundred persons infected in this Mwanza outbreak, travelling from the place of his infection, might "subsequently sit down and talk in a village or roadside halt in any tsetse belt in the territory in a locality in which man is for the time being the centre of attraction for the tsetse . . . and start a case or two or an epidemic." Swynnerton quotes evidence in favour of the view that it was in this way that the previous infections of *rhodesiense* in German East Africa started, and Duke also concludes that "the main danger to be avoided is the presence of infected natives in communities exposed to the tsetse."

It would seem that the practical question for future investigators will be less the conspecificity of the game and human trypanosomes (though this, and its importance, should be settled) than the prevalence of the human "carrier." Yorke has given an instance of a native laboratory assistant who, after *T. rhodesiense* had been found in his blood, was under observation for a year, and remained to all appearance perfectly well; it should be ascertained (not merely by blood examination, which may be unreliable, but by inoculation into susceptible animals) whether such cases are frequent. This seems of special importance at present, for natives from various parts of Africa have, in the course of the East African campaign, passed through the infected region of Portuguese Nyasaland, so that, if the human "carrier" should be a factor of importance, the ready-made *rhodesiense* strain may have been transplanted already to many places in which it did not previously exist.

Mr. Swynnerton describes the measures taken for the control of the outbreak. They included segregation of the sick and the evacuation of the area specially concerned, this last being rendered easy by the fact that it was surrounded by the tsetse-free areas of close settlement already referred to. He deals at some length with the general question of the control of the flies of the *morsitans* group, and in relation to the prevention of human trypanosomiasis points to the probable utility of a combination favoured by French investigators—namely, the sterilization of the sick by the administration of a suitable drug and the provision of a "screen" of immune animals. Due, but reasonable, game preservation would, he believes, in East Africa provide the "screen," and to guard against the untoward results of such local game destruction as might still take place he suggests that the natives might be required to place their villages in the centre of their cultivation and that small villages should be joined up so far as possible into large settlements in order that they may be surrounded by a larger cleared space and thus enjoy a greater immunity from heavy infestation by the tsetse flies. It would seem likely also, from Duke's observations in relation to ankylostomiasis, that due attention to this disease may in itself constitute a useful prophylactic measure in relation to sleeping sickness.

## British Medical Journal.

SATURDAY, MARCH 3RD, 1923.

## SIR CHRISTOPHER WREN AND MEDICAL SCIENCE.

Sunday, February 25th, marked the 200th anniversary of the death of Sir Christopher Wren. This "prodigy of learning" was born at East Knoyle, near the Somerset border of Wiltshire, on October 20th, 1632, where his father, Dr. Christopher Wren, was rector. He came of a learned and talented stock: his grandfather, Dr. Matthew Wren, had been bishop successively of Hereford, Norwich, and Ely; his father became Dean of Windsor. Wren was at school under Dr. Busby at Westminster, where he was contemporary with John Locke, who was just two months his senior. At the age of 13 he entered, as a gentleman commoner, Wadham College, Oxford. In his second year at Oxford his abilities attracted the attention of Dr. (afterwards Sir) Charles Scarborough, who was then lecturing in anatomy. Young Wren wrote with pride to his father in a Latin letter of his friendship with the "doctor." He assisted Scarborough as demonstrator in his anatomical lectures, and brought his mathematical knowledge, which was already remarkable, into play in studying the mechanics of muscular action. He composed later a treatise on the motion of the muscles, explaining the whole anatomy by models formed in pasteboard. They were presented to that eminent physician and his excellent friend Sir Charles Scarborough for use at the latter's celebrated lectures at Surgeons' Hall. These models were lost at the fire of London.

Dr. Plot, in his *Natural History of Oxford*, relates that among divers experiments in anatomy which Wren exhibited at the meetings at Oxford were schemes of fishes dissected . . . several things he observed very considerable in fowls. Some parts of animals he more exactly traced by the help of glasses, as the kidneys, the plexus in the brain, etc. The nerves he found to have little veins and arteries in them. He then found the lymphaducts to empty themselves into the receptacle of chyle, from all parts of the bowels, limbs, etc. Wren assisted Thomas Willis, too, in his anatomical dissections and demonstrations, and Willis testifies in the preface to his *Cerebri Anatome* that the illustrations in that book are from the pen of Sir Christopher Wren.

There can be no doubt that Wren's anatomical observations placed him among the first professors of the day. Sprat, in his history of the Royal Society of London, refers to him as "the first author of the noble anatomical experiment of injecting liquors into the veins of animals . . . by this operation divers creatures were immediately purged, vomited, intoxicated, killed or revived according to the quality of the liquor injected." Among the drugs with which he experimented in this way were scammony, opium, and wine. From these experiments he conceived the idea that blood might be transfused directly (and without coagulating) from the vessels of one individual into those of another. Aubrey quotes the Rev. F. Potter as stating that "at the Epiphaniae, 1649, when I was at his house, he [that is, Wren] then told me his notion of curing diseases, etc., by transfusion of blood out of one man into another, and that the hint came into his head reflecting on Ovid's story of Medea and Jason." This was an experiment which Wren took to be "of great concernment and what will give great light to the theory and practice of physick." But

it does not appear that Wren himself did more than suggest the possibility of direct blood transfusion. Richard Lower witnessed these experiments of injecting drugs into animals' veins, and evidently joined in discussions on the practicability of blood transfusion. It was left to him to devise a technique and put into practice for the first time Wren's suggestion. Lower added a complete chapter to his *Tractatus de Corde* (1669), in which he boldly claims priority for successfully transfusing blood from one dog into the veins of another. He describes how at Oxford, towards the end of February, 1665, in the presence of Dr. John Wallis and Dr. Thomas Millington, he demonstrated at the academy of medicine that the experiment could be safely performed. Lower does not include Wren among the spectators of the experiment which the latter had spoken of in 1649. But Wren may have been in Paris at the time, for he spent several months of 1665 in the French capital, where the plans for the Louvre, then in the course of building, won his ardent admiration. In the later part of that year he returned to London, and, like Glisson, Wharton, and a few other scientific spirits, he outstayed the Plague.

Although by now Wren was busily engaged in architectural work, his interest in anatomy and experimental medicine had by no means waned. In 1667 he wrote a letter to Scarborough in which he recounts some of his observations in this line, including the anatomy of the bones of the arm, dissections of the eel, and the operation of splenectomy in the dog. His inventions and apparatus covered nearly as wide a field as those of Leonardo da Vinci himself. He constructed a model of the eye, as large as a tennis ball, with the humours truly and dioptrically made; found a new way to grind glasses, invented new musical instruments, devised ways of submarine navigation, designed new offensive and defensive engines of war, and was the first to draw pictures of objects observed by microscopical glasses, as well as the inventor of the art of mezzotint engraving. The microscope, indeed, continued to attract his attention, and in 1677 we find him taking part in a discussion at the Royal Society on Leeuwenhoek's observations.

Wren's inaugural address before the Royal Society manifests his lasting enthusiasm for scientific medicine. There were three ways, he said, of obliging posterity—by advancing, first, knowledge; secondly, profit; and thirdly, health and conveniences of life. He foresaw the importance of studying the human organism from a biochemical standpoint: "Thus in the body of a man if we consider it only mechanically we may indeed learn the fabric and action of the organical parts, but without chymistry we shall be at a loss to know what blood, spirits and humours are, from the due temper of which (as of the spring in the barrel wheel) the motions of all parts depend." In this address he pays due tribute to Harvey's work, and outlines some of the subjects which might profitably be investigated by the Royal Society. Amongst medical subjects he mentions dissections, physiology, epidemical diseases, and diseases of grain, fruits, and grasses, with their effects upon animals. But although Wren still watched the onward march of natural science, his own labours henceforth lay in the field of architecture. His work in anatomy, physiology, and experimental medicine belonged to the earlier years of his life. How much medicine owes to his inventive genius can never be wholly known. What he achieved was important enough, what his contemporaries may have accomplished at his instigation can only be guessed at from such an example as Lower's successful experiments in blood transfusion.

Wren died in his ninety-first year; on February 25th, 1723, his servant, thinking he slept longer than usual after dinner, went into his apartment and found him

dead in his chair. His long life gave him for contemporaries all the wits, writers, artists, warriors, and ministers of the reigns of Charles I, Cromwell, Charles II, James II, William III, Anne, and George I. In his boyhood Evelyn, who met him at Oxford, had called him "that rare and early prodigy of universal science," and he never fell short of this early promise; to the end of his noble life he was distinguished for industry, love of art, placidity, modesty, communicativeness, and disinterestedness. Few men have been more generous in suggesting problems for others to work out; few, even among scientists, have cared less who claimed the fruits of their own genius. He wrote and published comparatively little. Hearne noted in 1713: "Sir Christopher Wren is a very great man, tho' he could never be persuaded to publish anything." In a French journal of 1750 he was described as possessing the failing, uncommon in an architect, of not knowing how to enrich himself. As a writer of to-day has said, "He was really an artist using the stuff of science as his material."

### BIOLOGICAL FOUNDATIONS.

DR. HALDANE, whose lecture on the fundamental conceptions of biology we print in this issue, has for many years devoted himself with conspicuous success to the investigation of the incredibly delicate mechanism by which the regulation of various physiological processes is effected in the animal body. When, therefore, we find him taking his stand against the mechanistic interpretation of life so familiar to physiologists at the present day, we must recognize the fact that he speaks with the authority derived from experience, and that his views are entitled to the most careful consideration. It is not altogether easy, however, on the basis of a single lecture, to determine exactly what those views are. There seems to be something rather elusive about them, and some will probably think that he is abandoning the safe ground of experimental science for the less secure foothold of metaphysics.

Dr. Haldane emphasizes the fact that biology is an independent science, of which physiology is one department—a fact that is too often lost sight of at the present time. The living organism, he tells us, is a whole which is something more than the mere sum of its parts, and must be studied and appreciated as such. No chemical and physical interpretation of its behaviour, however detailed, can give us a real insight into its nature. We welcome this reaction against the extreme materialistic tendency of some contemporary writers, but at the same time we cannot help thinking that he rather overstates his case, as when he tells us "that with neither the scalpel nor microscope as applied to dead organisms could structure be found that was capable of throwing light on any fundamental physiological activity." The remarkable nuclear phenomena accompanying cell division—to take only one illustration out of many—have surely thrown a flood of light upon the physiological activities involved in the processes of heredity, and yet these phenomena have been revealed to us almost exclusively by the microscopical study of dead organisms chemically treated. Possibly, however, the processes of heredity as thus revealed are not, in Dr. Haldane's opinion, fundamental. Perhaps nothing that is really fundamental is accessible by the methods of experimental science; but if so, biology, which depends entirely upon observation and experiment, can hardly be said to have any fundamental conceptions at all—for these we must look to metaphysics.

Although we by no means think that mechanistic interpretations can ever afford a complete explanation of

the living organism—or of anything else—yet it seems to us that they can take us a good deal farther than Dr. Haldane seems disposed to admit. He says that the mechanistic theory of life involves us in meaningless absurdities; but surely this is true only when it is pushed to a supposed finality. There is nothing necessarily absurd in a mechanistic theory of development. There is no need to suppose that the whole machinery of the adult organism is represented in some way in the fertilized egg. We need only assume that the germ plasm, being part of the same stock, is similar to that of previous generations, and that it is exposed during its development to similar conditions. The machinery develops gradually, as the result of the interaction between the developing organism and its environment, internal and external. The marvel is that the complex processes involved are regulated with such accuracy as to lead to practically the same result generation after generation. It is this wonderful power of regulation that constitutes the chief distinguishing feature of the living organism. The vitalists attempt to explain it by postulating a special vital force, which leaves us exactly where we were. Nor does the hypothesis of an indwelling soul help towards a scientific explanation. The mechanists alone are in a position to push the scientific analysis of vital phenomena to its farthest limits. Those limits have not yet been reached. In any case it must be left to the metaphysician to speculate as to things that are fundamental.

That the living organism is something more than a mere machine we can hardly doubt when we consider the phenomena of consciousness and intelligence as manifested in ourselves. At what point in the scale of evolution consciousness began to emerge we do not know. Nature knows no beginnings, only change. Dr. Haldane would exclude "the distinctive characters of conscious responses as such" from the domain of biological science and hand them over to psychology. But surely consciousness is the culminating manifestation of life, and if psychology is to make any progress as a real science it must be as a department of biology. What Dr. Haldane is really aiming at is the re-establishment of "the spiritual interpretation as the supreme interpretation of our universe." This is in no way inconsistent with the mechanistic interpretation of the living body. Science can never hope to explain anything completely, but that is no reason why she should not carry her explanations as far as she can. The wonderful progress in medical science, for instance, during the past century has been due almost entirely to mechanistic methods of thought and investigation, and the more these methods are developed and perfected the better will it be for the bodily health of the human race. The spiritual health is another, though a closely connected, problem, and perhaps a more important one, but it can hardly be dealt with in the same manner. From the broader point of view, however, nature and spirit are one, and there is really only one science, which we attempt to subdivide for our own convenience and in accordance with our own narrow limitations.

We could wish that Dr. Haldane had had time to elaborate his thesis from the evolutionary point of view, for it is to the study of evolution, in its broadest aspects, that we must look for more light upon the meaning of life. From this point of view the distinction between the living and the not living tends to disappear, and we find ourselves face to face with a continuous sequence of events that probably stretches back without interruption from the organic into the inorganic world. It would appear that as matter gradually acquired an ever-increasing complexity of structure, accompanied by repeated integration of lower units to form higher ones, so it gradually acquired new

properties, new methods of energy exchange. Each new product of integration was something more than the mere sum of the integrated units, and exhibited a characteristic behaviour of its own. At a certain stage of evolution, marked by the appearance of those extremely complex chemical substances which we call proteins, matter began to exhibit those particular energy relations which we have agreed to consider as distinctive of living things. One of the results of these complex energy exchanges between living matter—"protoplasm"—and its environment has been the further integration of units to form individual organisms, and the maintenance of its individuality, in spite of the disruptive tendencies of the environment, is, as Dr. Haldane rightly points out, one of the most distinctive features of the organism.

Dr. Haldane lays much stress upon the relativity of vital phenomena. The organism and its biological environment are inseparable, and exist only in relation to one another. To say, however, that life is not localized within the living structure of an organism appears to involve an extension of our ideas of life that would take us outside the customary limits of biological science. But, as we have already indicated, it is impossible to divide the field of knowledge into self-contained allotments. The chemist and physicist are concerned primarily with the inorganic world. The biologist is concerned with the world of living organisms, but he is bound to make use of the methods and interpretations of chemistry and physics to the very limit of their applicability. The speculations of the metaphysician must be based upon the results accumulated in all departments of science.

#### SCIENCE IN THE ARMY.

The appointment of Sir William Leishman to be the Director-General of the Army Medical Service is interesting, and one on which the Service and its Medical Corps is to be heartily congratulated. Sir William Leishman had active war experience as a young man during an Indian frontier expedition, and in the great war as Adviser in Pathology in France, until he was brought home in April, 1918, to occupy a similar position in this country. But it is as a pathologist and a man of science that he is known and honoured by the profession. It was in 1900 that he found the parasite now named *Leishmania donovani* in films taken *post mortem* from the spleen of a soldier who died in Netley from kala-azar contracted in India. Leishman did not publish his discovery until 1903, in which year Lieutenant-Colonel Donovan, I.M.S., observed the same parasite in blood obtained by splenic puncture during life. The discovery has revolutionized ideas with regard to kala-azar, a disease which during the last sixty years has spread widely in India. Sir William Leishman has also done important work with regard to tick fever, due to the organism of *Spironema duttoni*, conveyed by the tick *Ornithodoros moubata*. Finally, to make a long story short, we may note that his name is widely known as the deviser of a chromatin staining method, which is in general use in laboratories throughout the world. His position in the world of science is shown by the fact that he was an original member of the Medical Research Committee, now the Medical Research Council, and that he was elected F.R.S. in 1910, at the comparatively early age of 45. When the Directorates of Hygiene and Pathology were created within the Army Medical Department—a change effected by Sir John Goodwin in order that the Army Medical Service should cease to be divorced from current thought in pathology and preventive medicine—Leishman was obviously indicated for the appointment of Director of Pathology. It was frankly stated at the time that the Department was intended to furnish inducement to officers who had specialized in pathology to continue their work therein. Sir William Leishman's appointment to be Director-General is striking evidence of the deter-

mination to pursue this wise policy; evidence also that in the military services of the country, as well as in the civil profession, a man who will devote himself to science may attain to the highest position in the special department of medicine to which he gives himself. The Secretary of State for War may rest assured that his action is not only warmly approved by the civil profession, but will be a distinct encouragement to scientific workers in medicine.

#### TOOTH STRUCTURE AND DENTAL DISEASE.

In July, 1921, the Medical Research Council, in consultation with the Ministry of Health, appointed a committee, with Professor Halliburton as chairman, for the investigation of the causes of dental disease. The committee was asked to advise the Council upon the research work in this subject already aided by the Council and to initiate further researches. In presenting its first report on the structure of teeth in relation to dental disease,<sup>1</sup> the committee indicates its intention to issue reports upon other parts of the subject from time to time as completed. Mr. Howard Mummery, to whom this report is due, has considered his subject in three aspects: First, variations in the composition and structure of enamel and their relationship to dental caries; secondly, the production of artificial caries; and thirdly, arrested caries. Under the first heading he inquires whether enamel is entirely inorganic, and whether it is incomplete at the time of eruption and capable of further consolidation from without. Owing to the difficulty of microscopic examination of enamel, there are wide divergencies of opinion. Tomes is quoted in support of the view that there is no organic matter in enamel, whereas Lovatt Evans holds that there is 1 to 2 per cent. The reporter, unfortunately, attempts no explanation of these divergent findings. In discussing the second question he quotes one experimenter (Head) as of opinion that progressive consolidation may occur from dialysis of lime salts through Nasmyth's membrane, and another experimenter (Pickersill) as unable either to confirm or refute the experiments on which this opinion is based. The possibility of further consolidation from within, on the same lines as that seen in the enamel of sargus, the reporter thinks is indicated by certain microscopic appearances of the amelo-dentinal junction—spindles and bundles of apparent fibrils which take a stain. The possibility of further consolidation of the enamel after eruption of the tooth may prove of great import in the prevention of dental caries; Mr. Mummery's attitude is non-committal, and does not inspire much hope. From the report it is not easy to gather what variations are considered normal and which are defects, but the impression given is that if the teeth are kept clean the variations are all immaterial. The report on the production of artificial caries is chiefly historical. It is short, but brings into prominence the chief workers in this field, giving honour where honour is due. The important point is that caries "indistinguishable both macroscopically and microscopically from natural caries" has been produced in the laboratory by initiating ordinary food stagnation in the human mouth. The section on arrested caries of the teeth does not seem to warrant the hopeful attitude taken up by some of the lay press. It is pointed out that the stained surface of dentine showing arrested decay is more resistant to acid than unstained dentine, and that beneath this is a "translucent zone" of dentine also more resistant to acids; but it has to be admitted that unless the enamel be removed around and beyond the area of decay, decay will spread laterally in the amelo-dentinal junction, and what is gained in one direction will be lost in another. The comparatively insensitive temporary teeth may lend themselves to this very old treatment of "filling out the decay," but the sensitive permanent teeth present quite another problem. Certain appearances found by Mr. Mummery in sections of decaying enamel suggest that in this tissue also a translucent zone may be formed. The suggestion is that this, like the translucent zone

<sup>1</sup> The Structure of Teeth in Relation to Dental Disease, by J. Howard Mummery, C.B.E., D.Sc., M.R.C.S., L.D.S., Medical Research Council Special Report, No. 70, 1922. H.M. Stationery Office. (2s. 1d. 2s. 18 figures. 2s. net.)

of dentine, may represent a vital reaction and an attempt to interpose a barrier of more fully calcified tissue to the advancing caries; but Mr. Mumery asks for further investigation before drawing any such conclusion. The report is beautifully and pertinently illustrated, and is provided with a list of references. One reference, however, which might well be of interest to investigators is missing. Where is Rudas's note on the finding of magnetic iron in the enamel of diluvial teeth to be found?

#### ATMOSPHERIC CONDITIONS IN COTTON WEAVING.

In Report No. 21 of the Industrial Fatigue Research Board Mr. S. Wyatt describes the investigations he has made on the atmospheric conditions in nine large weaving sheds. The subject is of great practical importance, because of the artificial conditions under which a great deal of cotton weaving is carried on. In order to improve the quality and quantity of the cloth woven the air is humidified by blowing in steam, and frequently the wet bulb temperature is allowed to rise within 2° F. of the dry bulb temperature. The summer observations in humidified sheds showed an average dry bulb temperature of 75°, and a wet bulb temperature of 70°, though in two sheds the average wet bulb was 73.4°. Needless to say, this system of "steaming" has caused many complaints among the weavers, and there have been demands for its complete abolition. Short of this it is clearly the duty of the employers to neutralize the evil, so far as possible, by maintaining good ventilation. Mr. Wyatt made a large number of determinations of the air currents in the sheds by means of the kata-thermometer, and he found there was considerable uniformity in the various sheds, the average velocity, both in summer and winter, being 26 feet a minute. This value compares favourably with the observations made by other investigators in certain industries, such as the pottery industry (potter's shops) and the printing trade, but it is by no means adequate, for the large number of observations made in boot and shoe factories gave a considerably higher figure—namely, 36 feet a minute, on an average. In humidified sheds, therefore, the manufacturers ought to improve the ventilation till the air currents have a velocity of 50 feet a minute, or more, and in so doing they would afford considerable relief to the weavers. In addition to improving the general ventilation it is probable that much can be done by a system of local ventilation. Mr. Wyatt has shown that the air movement in the vicinity of the weaver can be greatly increased by attaching a three-inch strip of canvas to one of the moving parts of the loom.

#### THE HOME AMBULANCE SERVICE.

THE Home Service Ambulance System, organized by the Joint Committee of the Order of St. John and the British Red Cross Society, has now become well established. It may be remembered that it arose out of the fact that when the war came to an end a large number of motor ambulances which had been in use in France were returned to this country; some of these are still in use, but it has been the policy of the Home Service Ambulance Committee to make renewals whenever necessary. There are now ambulances stationed in forty-six counties in England, and thirteen in Wales; during the last quarter of 1922 seven new ambulance stations were opened, and there are now altogether 320. During the same period four stations were, for various reasons, closed. The steady increase in the number of patients carried in the ambulances at the great majority of stations shows that recognition of the value of the service is spreading, and that medical men are taking advantage of the facilities offered for the removal of patients. There are still, however, a small number of stations where the ambulances carry so few patients that it seems probable either that adequate steps have not been taken to make the existence of the ambulance known, or that local regulations as to the conditions for its use act as a deterrent. The demand

for ambulances throughout the country is still so keen that it would not be just to continue the loan of cars to localities in which they are not used to the fullest extent possible, and the Committee, in such cases, has no alternative but to ask county directors to close the station so that the ambulance may be transferred elsewhere. The Committee fully appreciates the fact that good and efficient service has been done at a great number of stations where, though the work may be spread over a wider area and entails a greater mileage, a smaller number of patients have been dealt with than in such localities as West Lancashire, where since the Service was instituted eleven ambulances have carried over 26,000 patients, and the West Riding, where twelve ambulances have carried nearly 12,000. The total number of cases carried now averages over 50,000 a year. The ambulances are manned by members of the Order of St. John or the British Red Cross Society, and it is intended that any new station shall be in charge of representatives of one or other of these constituent bodies.

#### X-RAY MEASUREMENT AND PROTECTION.

A JOINT meeting of the Röntgen Society and the Physical Society was held on February 23rd to discuss the physical aspects of the problems involved in the measurement of x rays. The demonstrations and papers were concerned chiefly with methods of measuring x-ray intensity and with the quality of x rays produced by various types of high-tension generators, and therefore scarcely lend themselves to summary in a manner interesting to the ordinary medical radiologist, although of great ultimate importance to him; moreover, as Sir William H. Bragg reminded the audience, it is a long way from the laboratory, where one wave-length can be separated from another, to the treatment room, where a great number of different conditions have to be allowed for, the relative effects of each of which are hard to disentangle. Not very much work, he said, was being done in this country on x rays from the physical point of view, for in fact not many physicists were working on x rays at all. The contribution of most immediate interest to the medical man was made by two physicists, Dr. G. W. C. Kaye and Dr. E. A. Owen of the National Physical Laboratory, who have been examining a large number of x-ray protective materials submitted to the laboratory for test, consequent upon the recommendations drawn up by the X-Ray and Radium Protection Committee (under the chairmanship of Sir Humphry Rolleston) for the better protection and general improvement of the working conditions of the x-ray operator. This Committee recommended that the protection afforded by a material should always be referred to in terms of the equivalent thickness of lead. This use of lead as a standard of reference had proved convenient, and gave the approximate accuracy which suffices in practice, when dealing with composite or laminated materials, as the lead values of the several layers could be regarded as additive. When the exciting voltage was over 100,000, the Committee recommended a protection equivalent to 3 mm. of sheet lead, and with exciting voltages below 100,000 a thickness of not less than 2 mm. In modern x-ray therapy, as Dr. Finzi observed in the subsequent discussion, the radiations, according to the findings of the physicists, are from 200,000 volts upwards. With these requirements in mind, Drs. Kaye and Owen determined the "lead equivalents" of a variety of materials. The results obtained were for x rays generated by 100,000 volts with a tungsten target, but the values hold good over a considerable range on either side of this figure, and are ordinarily diminished by from 5 to 10 per cent. when the voltage is only 50,000. A number of samples of building materials were included in order to discover the protection afforded by the walls and floors of x-ray departments. It was found that 1 mm. thickness of bricks or concrete was equivalent to about 0.01 mm. thickness of sheet lead, so that the equivalent of 3 mm. of lead would be a 300 mm. (12 in.) solid concrete floor. The majority of woods had only about one-tenth of the "lead value" of

bricks and concrete, and about 20 mm. ( $\frac{3}{4}$  in.) of steel plate would be required to give a protection equal to 3 mm. of lead. The lead equivalents of baryta plasters, which there is some tendency to use at the present time, were also determined. The thickness of a mixture in equal parts of barium sulphate, sand, and cement would have to be 60 mm. (nearly 2½ in.) to give a protection equal to 3 mm. of lead; the weight of the plaster is nearly three times that of lead. Rather less forbidding results were obtained with another mixture consisting of one-third coarse barium sulphate, one third fine barium sulphate, and one-third cement. The investigators criticized the open lead-glass bowl used as a container for the x-ray bulb. Owing to its design it might afford no protection whatever in certain directions. Such a bowl, in their view, should be provided with some kind of cover and made more effective. For screens or windows glass of the highest lead values was inadmissible on account of the impossibility of producing it in flat sheets free from streakiness and colour. It was necessary to turn to glass of a lower lead content, and which could be obtained in sheets perfectly flat, of great clarity, and almost colourless. The lead value of such glass was only about 0.12 for each millimetre, but as sheets up to 18 mm. thick could be obtained the requisite protection was readily afforded, though the weight was considerable. For aprons and gloves in which lead rubber was employed the Protection Committee recommended a minimum lead equivalent of 1.2 mm.; it was found that 1 mm. of lead rubber was equivalent to a thickness in sheet lead of 0.25 to 0.45 mm. Drs. Kaye and Owen laid stress upon the fact that different makes of lead rubber differed in protective value by 100 per cent. Papers were read also by Mr. W. E. Schall, Dr. F. L. Hopwood, who gave a demonstration of the endoscope, and others, and Professor Sydney Russ suggested some executive action by the councils of the two societies with a view to setting up an international measure of radiation.

#### SOCIETY OF RADIOGRAPHERS.

We have received from the Society of Radiographers a pamphlet setting out the objects of that body. The Society was founded two years and a half ago with a view to giving a definite professional status to those certificated non-medical assistants who work in x-ray and electrotherapeutic departments. Its aim is to comprise those approved persons at present working at the subject, and to certify new workers after due training and a strict examination. The constitution of the Society was drawn up by a joint committee containing representatives of the British Association for the Advancement of Radiology and Physiotherapy; of the Institution of Electrical Engineers; and of radiographer-assistants themselves. By general consent the term "radiologist" has come to be applied to members of the medical profession who undertake radiographic diagnosis, and treatment by means of x rays and radium; while the term "radiographer" denotes their trained non-medical assistants. It is laid down in the constitution of the Society that its members shall not undertake treatment in any shape or form except under the direction of a qualified medical practitioner, thus conforming with the spirit of a resolution of the Council of the British Medical Association passed on October 24th, 1917: "It is not desirable to encourage the practice of medical radiography by lay persons, except under the direct instructions and supervision of medical practitioners." Paragraph 27 of the constitution of the Society of Radiographers, which runs as follows, seems sufficiently explicit: "No non-medical member (i.e., no member who is without the qualifications entitling him to practise in Great Britain or Ireland as a physician or surgeon) shall accept patients for radiographic, radioscopy, or therapeutic work except under the direction and supervision of a qualified medical practitioner, and any breach of this regulation shall be deemed conduct unfitting the member guilty thereof to remain a member of the Society." The Society now numbers some 120 members. It is governed

by a council comprising members of the three bodies from whom the joint committee was formed. The president is Sir Archibald Reid, superintendent of the x-ray department of St. Thomas's Hospital; the vice-presidents are Dr. Robert Knox, honorary radiologist to King's College Hospital, and Mr. C. H. Wordingham, formerly president of the Institute of Electrical Engineers. An examination in the practical and theoretical side of the work is held twice a year, successful candidates receiving the diploma of member (M.S.R.). Hospitals are invited to co-operate with the Society in maintaining a high standard of technical efficiency by employing only duly qualified persons as assistants in their x-ray departments. An information bureau has been formed in order to bring together radiographers and institutions needing their services. Communications may be addressed to the Secretary, Society of Radiographers, 12, Stratford Place, W.1.

#### THE WREN CELEBRATION.

We refer elsewhere to Sir Christopher Wren's observations on physiology, which were of very considerable originality and importance; we will here only briefly mention the ceremonies which have taken place this week to commemorate the second centenary of his death. One of these, and perhaps the most striking, was the service at St. Paul's Cathedral on Monday, which was attended by many representatives of the City of London, of architecture and art in general, and of the medical profession. After a short service a procession was formed to the crypt, where Mr. Paul Waterhouse, President of the Royal Institute of British Architects, laid a wreath on the tomb, and M. Augustin Rey, on behalf of the Société Centrale des Architectes Français, deposited a bronze palm; a wreath was sent by the French Société des Architectes Diplômés. A representative of the American Embassy in London also laid a wreath on behalf of the Architectural League of New York. The Dean of St. Paul's then gave a short address. He began by saying that those present had assembled to do honour to one of the greatest of Englishmen, in a building which was the greatest triumph of his generation. Wren's building had accumulated more glorious memories than Old St. Paul's, because that was the centre of a little country, whereas Wren's St. Paul's was the metropolitan cathedral of the greatest empire in the world's history. Among those who attended the ceremony was the President of the Royal College of Physicians, and it may not be out of place to recall that the house of the College of Physicians contains at least one remnant of Wren's work. The home of the College in Amen Corner was destroyed in the great fire of London, and the new house in Warwick Lane was designed by Wren. Dr. Baldwin Hamer, who contributed liberally to the funds for the rebuilding, defrayed also the cost of wainscoting the coenaculum with fine Spanish oak, presenting fluted pilasters, ornamented capitals, and elegantly carved cornices. In 1820 Wren's building had become not only inconvenient, owing to its situation, but had fallen into dilapidation, and Sir Henry Hallford, who was elected president in that year, brought about the removal of the College in 1825 to the building it now occupies in Trafalgar Square. Care was taken to remove part of the wainscoting given by Hamer, and it now furnishes the Censor's room. Although there is no positive evidence, the opinion of experts, and the fact that Wren was in the habit of employing Grinling Gibbons, combine to make it almost certain that the carving is by Gibbons.

#### TREATMENT OF OPHTHALMIA NEONATORUM IN LONDON.

In the report of the Departmental Committee on the Causes and Prevention of Blindness attention was drawn to the different practices adopted in Liverpool and London for the reception of mothers and infants when the infant suffered from ophthalmia neonatorum. Liverpool arranged for the reception of the patients in one of the existing voluntary hospitals, in London a special hospital was set up by the

Metropolitan Asylums Board, the St. Margaret's Hospital. The departmental committee thought there was some disadvantage in a special hospital, which may come to be regarded as primarily associated with venereal disease, with a consequent unwillingness on the part of some mothers to enter such an institution. Further, it was thought that a single hospital in London was not likely to be sufficiently known to practitioners and people. For these reasons it was considered that in London it would be advantageous that hospital accommodation should be provided by securing beds in a few of the well known teaching hospitals in centres convenient to the great masses of the population. There would be a further advantage in such an arrangement, in that students attending the practice of these hospitals would become familiar with the care and treatment of these cases, which they will not readily do if provision is made at one special hospital alone. We have now received from Mr. M. S. Mayou, F.R.C.S., the statistics of the number of cases notified in the metropolitan area and the number admitted to St. Margaret's Hospital, which is situated close to the Kentish Town Station of the Midland Railway:—1919: cases notified, 870; cases admitted, 281. 1920: cases notified, 1,186; cases admitted, 252. 1921: cases notified, 1,076; cases admitted, 213. 1922: cases notified, 866; cases admitted, 213.

#### DISTEMPER RESEARCH COMMITTEE.

As has already been announced, the Medical Research Council has undertaken to organize an investigation into dogs' distemper, towards which funds will be provided by the Field Distemper Council. Researches will be conducted by members of the Medical Research Council's staff, partly at the National Institute for Medical Research, Hampstead, but more particularly at the new farm laboratory, for which a site near London has recently been acquired. As opportunities arise and suitable assistance can be secured, inquiries co-ordinated with these will be promoted at other centres of work. These investigations will also be brought into relation with other studies in human and animal pathology. The Medical Research Council has appointed the following scientific committee to advise on the subject and to direct the investigations: Sir William B. Leishman, K.C.M.G., C.B., F.R.S., Director of Pathology, War Office, and a member of the Medical Research Council (Chairman); Mr. J. B. Buxton, F.R.C.V.S.; Captain S. R. Douglas, F.R.S., National Institute for Medical Research; Professor F. Hobday, C.M.G., F.R.C.V.S.; and Dr. C. J. Martin, C.M.G., F.R.S., Director of the Lister Institute. Other members may be added later as the programme develops. A member of the Council's staff will act as secretary to the committee, and communications upon any scientific questions should be addressed to the Secretary, Distemper Research Committee, 15, York Buildings, Adelphi, W.C.2.

#### OSWALDO CRUZ.

DR. BELISARIO PENNA has fitly chosen the first centenary of the Independence of Brazil for the publication of his recollections of Oswaldo Cruz, whose disciple he was. Cruz, perhaps the most illustrious of Brazilian men of science, died of Bright's disease in 1917 at the early age of 44. For fifteen years he laboured incessantly in the domain of sanitary science, and to him Brazil is indebted for its rapid emancipation from yellow fever. As director of the Brazilian Public Health Service he stamped out this disease in less than three years, and was equally successful in dealing with yellow fever in Para, the principal seat of the rubber industry on the Amazon. He also carried on a vigorous campaign against plague, malaria, and small-pox, which were very prevalent throughout the country. In 1900 he founded an institute for bacteriology and serum therapy, to which in 1908 the name Instituto Oswaldo Cruz was given. It is one of the finest institutes of parasitology in existence, and its proceedings, which are issued annually in Portuguese and French, are well known to biologists throughout the world. By means of

this institute Oswaldo Cruz was able to found a school of hygienists and workers in experimental medicine, of whom the best known is probably Carlos Chagas, who discovered the cause of chronic infective thyroiditis. Dr. Penna has reproduced a number of portraits of Oswaldo Cruz, but does not attempt to give any continuous narrative, contenting himself with a collection of extracts from articles, lectures, and addresses; but we sympathize with his fervid panegyric of this great Brazilian scientist.

THE Council of the Royal Society of London has recommended fifteen persons for election into the Society: they include Dr. E. D. Adrian, University lecturer in physiology, Cambridge; Dr. Edward Fawcett, professor of anatomy in the University of Bristol; Dr. R. T. Leiper, professor of helminthology in the University of London, and Director of the Department of Helminthology in the London School of Tropical Medicine; Dr. J. J. R. Macleod, M.B., Ch.B. Aberd., professor of physiology in the University of Toronto. Among the other names are those of Dr. Guy Marshall, Director of the Imperial Bureau of Entomology, and Sir Douglas Mawson, D.Sc., who led the Australasian Antarctic expedition, 1911-14.

THE Section of Medicine at the Annual Meeting of the British Medical Association, to be held this year at Portsmouth, will meet on Wednesday, Thursday, and Friday, July 25th, 26th, and 27th. The Committee of the Section, of which Sir Thomas Horder is president, has decided that the subject to be discussed on the first day shall be diabetes; on the second day there will be a discussion on the etiology and treatment of heart disease in early life, with a special view to the prevention of chronic cardiac insufficiency; and on the third day a discussion on chronic bronchitis.

### Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

#### Pension Medical Services.

TRIBUTE BY THE MINISTER OF PENSIONS. MAJOR TRYON, the Minister of Pensions, made an important speech on February 20th in meeting a motion in the House of Commons for a Select Committee of inquiry into the work of the Pensions Ministry. The motion was submitted on behalf of the Labour party by way of amendment to the address by Mr. Adamson, who traversed familiar ground; a number of other members raised points of criticism, but did not make any personal reflections on the medical services.

The Minister of Pensions spoke first of the enormous medical responsibility of his Department for the care of the sick and wounded. The nation, he said, owed a great debt to the medical profession and the hospital staffs for what they had done, and he was sure the House would feel that no expenditure could be devoted by the country to a better purpose than to the restoration as useful citizens of those who had been disabled in the great war.

#### Definitions of Terms.

To clear up misconceptions that might still obtain, Major Tryon recapitulated primary definitions. He reminded the House as regards the term "entitlement" that the grant of pensions was made entirely irrespective of what employment a man might get. The entitlement was simply the right of compensation for the disability suffered. "Assessment" was the measuring by medical authorities of the extent of the disablement, comparing it with the condition of a normal healthy man of the same age. It was expressed in percentages. There was no other way in which assessment could be made. In respect to the pensions scale or rate, he was sometimes told that the Government had not done its duty to the ex-service men. Before the war an ex-service man, totally disabled, with a wife and two children, cost 17s. 6d. Now in such case the scale provided was 63s. 6d.

#### Appeal Tribunal.

The ex-service men had demanded and maintained the demand that the question of entitlement, whether the injury was due to the war or not, should be settled by some impartial tribunal—should be taken absolutely out of the hands of the Ministry of Pensions—and that was why the Lord Chancellor's Department had been chosen to set up

a number of these tribunals for entitlement. They consisted of a lawyer of seven years' standing, an ex-service man, and a doctor. He did not know of any other country in which the decision vitally affecting State funds was thus taken away from the control of State officials and put in the hands of three persons who could absolutely decide the issue.

#### *The Medical Boards.*

Statements had been made that secret instructions had been issued to these Boards to cut down pensions. A Departmental Committee upon which were representatives of the three great ex-service men's organizations, a member of the Labour party, members of every other party in that House, and representatives of the local voluntary workers, had thoroughly investigated the allegation, and they unanimously agreed that there was no truth in it. Members of Parliament frequently quoted cases where Medical Boards cut down the rate of pensions, but said nothing about those of enlargement. The main justification, in his opinion, for the Medical Boards in the last year or two had not been any reduction that might have been effected, but the fact that as some men were getting better and some men were getting worse, it was necessary to make adjustments. If these men were not examined, simplicity would be obtained at the cost of the men who were getting worse. The country would be spending its money, not on the men who were getting worse, but on those who were getting better. Over the whole range of cases the effect of the work of the Medical Boards had been remarkable. About two years ago, taking the increase in respect of cases getting worse, and the decrease in respect of those getting better, the net reduction of assessment by the Medical Boards was 6 per cent. A little time ago the net reduction, as the result of the service of the Medical Boards, was 4 per cent. The net reduction of assessment to-day was 3½ per cent. The lesson of these figures was that the Ministry was right when in 1921 it introduced the Pensions Bill of that date giving increased powers to grant final awards, because it was found that about 50 per cent. of the cases examined showed no change. The advantage of the power to grant an increased number of final awards was that the pensioner with his affairs thus settled felt that his pension was safe for the rest of his life. At the present time final awards were being made at the rate of 4,000 a week.

#### *Cost of Administration.*

A Departmental Committee had sat for seven months in order to ascertain what could be done in reasonable economy. The Medical Subcommittee introduced the system of clearing houses for the sick and wounded. The result was a saving of time, a lessening of the waiting list, and great financial economy. A saving of £250,000 was also made by reducing the number of doctors on Medical Boards from three to two. Legislation would be proposed this session under which a pensioner, instead of having to produce a life certificate every three months, would have to do so every six months only. That would get rid of an enormous amount of trouble to all concerned, and would save about a million a year in expenses of the issue office. Finally, in this connexion, Major Tryon mentioned with satisfaction that the cost of administration, apart from medical administration of medical service, was down to as low a rate as 9d. in the £. Moreover, 97 per cent. of the male staff were ex-service men, and that, he thought, met any suggestion that there was want of sympathy in the Department.

#### *Medical and Surgical Work.*

Major Tryon regretted that he had not more time to speak in detail of the medical and surgical work, but he gave some striking information. Since the armistice the Ministry had spent over £60,000,000 on the medical treatment of the sick and wounded of the great war, and in allowances for the men and their families while the treatment continued. The nation would, he felt sure, be grateful to the medical profession and hospital staffs for the remarkable results achieved. A large proportion of the patients had been restored to health and had resumed their civil occupation. At the present time the Ministry was responsible for—

A daily average of 25,000 patients in hospital (of these, 12,000 are in hospitals owned, managed, and staffed exclusively by the Ministry);

A daily average of 80,000 patients attending as out-patients at hospitals or clinics (of whom the larger number are attending clinics owned, staffed, and controlled exclusively by the Ministry);

Over 1,000,000 cases of treatment have been given by the Ministry in the past three years.

It must not be supposed that these cases simply went under treatment and came out again as quickly as possible. It was the aim of the Ministry's medical service to continue treatment so long as there was the smallest chance of material improvement in the man's condition. As an illustration of

the care taken he mentioned that he had recently had an investigation made into a batch of 2,000 cases, and had found that 40 per cent. had been receiving treatment, whether as in-patients, out-patients, or at home, at the expense of the Ministry, for eighteen months and over. They were cases, many of them, of gunshot wound, requiring orthopaedic treatment; some were tuberculous; many were neurasthenic. The medical service of the Ministry was not only the largest of its kind, but was by far the most comprehensive in technical equipment. The work done in the Ministry hospitals—for example, for surgical cases by orthopaedic treatment—was far ahead of anything else in the country in comprehensiveness. He had had an analysis made recently of 1,000 cases taken at random of the discharged from hospital during the last twelve months. The figures came out as follows:

General medical and surgical cases—118 out of 224 were discharged as completely recovered.

Tropical disease cases (dysentery, malaria, etc.)—51 out of 55 men discharged were either recovered or greatly improved.

Orthopaedic cases—185 out of 452 were discharged as recovered and 199 were discharged as greatly improved.

The treatment and handling of ex-service men suffering from nerve or brain trouble had been constantly under discussion between himself and representatives of ex-service men. There were three points on which they were specially concerned—the hope of cure for those already in asylums, the efforts being made to save border-line cases from having to be certified, and the restoration to health and usefulness of the mental and nerve cases. His predecessor and himself had realized fully the importance of this question, and had gone a long way to meet it. The Ministry had fourteen neurological hospitals and a large number of neurological clinics. These were staffed with the best experts, and the special emphasis which the Ministry had given to this branch of treatment had actually led to a very great increase in the number of such experts, many of whom would not have taken up this class of work but for the training given in Ministry hospitals. The Ministry had actually by its neurological work in hospitals and clinics prevented a very large number of cases becoming certified. In these hospitals and clinics every class of case was dealt with, from the slightly neurasthenic to those on the border-line, and efforts in treatment did not cease until a definite cure or substantial improvement wherever possible was shown. In one neurological hospital devoted to the most serious cases, out of 134 treated during 1922 only nine had eventually to be certified as insane; of the remainder, 68 were discharged recovered, and twelve were transferred to other institutions, including some for industrial training. At another Ministry hospital, out of 300 cases treated during the twelve months, 246 were discharged medically reported as recovered, and it was known that 121 got employment at once, while some of the remainder were transferred to the Ministry of Labour for training, or, with the help of the War Pension Committee, were given grants to set up in business. Between 1,500 and 1,600 cases passed through the neurological hospitals in a quarter. Of these on an average 20 per cent. were discharged fully recovered. He thought that the medical staff might find great pleasure in the photographs sent in token of gratitude from men who had appeared shattered wrecks, but had now emerged into civil life—to be useful citizens and happy men. Some of the best treatment given had been in teaching the man a trade—not necessarily a trade that he would follow, but for its value in curative effect.

In conclusion, Major Tryon announced that the Ministry was going to start as an experiment separate arrangements for the treatment of selected certified cases of a hopeful type. The Government felt that the experiment was well worth making. A beginning would be made tentatively with one or two small establishments, and steps were being taken to start at an early date. In thanking Members of Parliament for the help they had rendered to the Ministry, Major Tryon said this was a nation's debt, and it should be the duty of all parties in the State to assist in meeting it. The division showed a majority of 131 for the Government, the amendment being rejected by 307 votes to 176.

#### *Institutions for Mental Defectives.*

In Committee of Supply, on February 21st, a token supplementary vote of £10 was proposed in respect of work being under taken in the enlargement of the Rampton Institution for Mental Defectives. Sir John Baird explained that the provision was for defectives who had violent propensities. The existing building accommodated 220 males and 148 females. The scheme was for the erection of an additional unit to accommodate 99 persons and additional nurses, and cottages for the married staff. Three years would be required to carry it through. The administration was by the Board of Control.

In the course of discussion several speakers suggested that it would be better to have several small buildings rather than one large institution, and Mr. Pringle recalled previous estimates for

this institution; in 1921-22 there was one for £35,700 for a new female wing; in the following year the expenditure upon a wing for patients and on improved accommodation for nurses reached £51,200. There was now a further estimate amounting to £109,000. Sir John Baird admitted the existence of a difference of opinion among experts as to the relative value of treatment in large and in small institutions. The Board of Control was of opinion that an institution such as that under discussion was best adapted for the purpose. Dr. Chapple inquired whether the Minister had exhausted the possibility of using some of the derelict buildings to be found all over the country. He knew of one that cost over £100,000 to build, that had been comparatively recently bought by the Government, which was anxious now to sell it for £22,000, but there was no offer. He disagreed, however, with those who denounced institutional treatment, and thought it was generally desirable.

Sir Sydney Russell-Wells said that if there was one lot in life deserving commiseration more than another it was that of the man, woman, or child who came within this class of mental cases. Any attempt to interfere with the treatment of such persons, or to lessen the facilities for dealing with them, was to be deprecated, for such treatment was a benefit not only to the sufferers but to the nation. The saving of abuses was far more likely to be achieved in large than in small institutions, for the large had greater facilities for classifying, grading, and arranging the inmates. He asked members to recall villages in the country where in days gone by—perhaps even now—there was a village lunatic who was the butt of the children. Was it suggested that a poor wretch of this sort would not be better off in an institution? Such a place was better than the patients' own homes or a small institution. A great deal more money might be spent in adapting existing buildings than in providing new. Possibly mental deficiency was the most frequent cause of abnormal and extraordinary crime. Persons had been sentenced as criminals when they ought to have been treated as mental deficients. The vote was carried by 248 to 132.

**Voluntary Hospitals' Grant.**—Sir W. Joynson-Hicks informed Mr. Gilbert, on February 21st, that the whole of the sum of £500,000 granted to the Hospital Commission had not yet been distributed. ... to hospitals in London, and the ... tributed. The sum of £275,000 ... tside London. Of this £181,318 had been paid to date, and the Commission intended shortly to consider the distribution of the balance after the claims in respect of the 1921 deficit had been met. The Commission had not yet made any recommendations as to the continuance of State assistance after the grant was exhausted. Full information in regard to the work of the Commission was contained in the interim report which was being issued that week. The Ministry of Health had no responsibility for the combined appeal for the hospitals in London, but it had been informed by the organizing committee that it was not yet possible to state exactly the total sum contributed to the combined appeal. The sum actually paid in to the organizing committee amounted to £392,100, of which £269,000 had been contributed. But large additional sums had yet to be received from two schemes which were still open.

**Medical Treatment for Ex-service Men.**—Viscount Windsor asked, on February 21st, whether the Minister of Pensions would make arrangements in country districts—in order to obviate the long delay and physical injury which were often entailed—for ex-service men to be examined and treated by a local medical practitioner instead of having to apply to the local Ministry of Pensions office in the event of recurring illness. Major Tryon said it was the recognized duty of a local insurance practitioner to refer a patient to the local office of the Ministry if he considered that the man required special treatment of any kind for a war disability. It was competent for any disabled ex-service man to apply direct to the local office of the Ministry for this purpose.

**Institutions for Tuberculous Patients.**—On inquiry by Mr. Briant, Sir W. Joynson-Hicks stated, on February 21st, that the institutions approved by the Minister of Health for the treatment of tuberculosis in England, apart from Poor Law institutions, contained 19,240 beds. Of these, 3,310 were in children's institutions, but the remaining 15,930 were available for insured persons, although since the termination of sanatorium benefits no beds were specially reserved for such patients.

**Spaulding Treatment of Tuberculosis.**—Captain W. Benn asked the Minister of Pensions, on February 20th, whether his attention had been called to the Spaulding treatment for tuberculosis, and whether it was intended to make it available for ex-service patients. Sir W. Joynson-Hicks, in reply, said that the Minister of Health was informed that no supplies of M. Spaulding's remedies were yet available in this country. When they became available it would be open to the medical officers responsible for the treatment of ex-service men to utilize these remedies in the treatment of their patients if they considered it desirable.

**Legislation as to Mental Treatment.**—Mr. Griffiths asked, on February 26th, whether a bill would be brought forward this session to extend to other local health authorities the powers already conferred by the Public Health Act, 1875, on borough councils to conduct hospitals for any class of illness, including early uncertifiable cases of nervous breakdown; and whether, in view of the urgent need for hospitals of this description unconnected with lunacy administration and free from detention, the Minister of Health would extend the grant to enable councils to maintain such hospitals, with a view to the reduction of the £7,900,000 now spent annually in keeping up asylums. Sir W.

Joynson-Hicks said that the question of introducing legislation with regard to mental treatment was receiving the consideration of the Government.

**Visitations to Mental Hospitals.**—Requested on February 26th to take steps to see that Section 79 of the Lunacy Act was posted up in the waiting room of asylums, Sir W. Joynson-Hicks said that all mental hospital authorities had been asked to set out the effect of Section 79 of the Act in the regulations as to visitation which were sent to friends of patients. The Board of Control considered this preferable to putting up a notice in the waiting room.

**Health Insurance: Medical Benefits.**—Sir Kingsley Wood asked, on February 20th, whether in view of the expiration of the agreements at the end of this year with doctors on the panel list, the Minister of Health was taking steps to review the present scheme of medical benefits with a view to rendering it more efficient and economical. Sir W. Joynson-Hicks said that the existing arrangements were now being examined in detail by the Insurance Consultative Council of the Minister of Health.

**Maternity Service and Child Welfare in Scotland.**—Captain Elliot informed Mr. Sullivan, on February 22nd, that the amount of Government grant paid in relief of local authorities' expenditure in Scotland under schemes of maternity service and child welfare, in each local authority financial year ending in May, was in 1919-20 £64,692, in 1920-21 £90,532, and in 1921-22 £235,832. The gross expenditure of local authorities in each year would be almost exactly double the amount of grant. The figure given for 1921-22 was an approximation. The very large increase of grant in that year was due in the main to the increased supplies of food and milk given by local authorities, the cost of which amounted to more than half of the total expenditure. The grant for 1922-23 could not yet be stated, but it was not expected to exceed £111,000.

**The Registration of Nurses.**—Mr. Briant asked, on February 21st, if the proposals of the Nursing Council included the registration of nurses with less than (the interests of the public, w efficiency, the Minister c reduction in the standard of nursing. Sir W. Joynson-Hicks said that the Council had submitted a rule which had for some time been in operation in Scotland, to give it a discretion in exceptional cases to admit nurses with less than one year's training. The Minister had asked the new Council to reconsider this proposal, and until its reply was received it would be premature to make any statement.

**Unemployment and Sickness.**—Questioned by Mr. Somerville, on February 21st, whether there had been increase of sickness from lack of sufficient nourishment, Sir W. Joynson-Hicks said the latest figures available as to the expense of sickness amongst persons insured under the National Insurance Acts indicated that the aggregate amount of sickness during the past year fell short of the expectations on which the Acts were based, and also of the experience of any pre-war year. So many factors affected the total expenditure on sickness benefits that it was impossible to assign variations in that figure to particular causes. But there was no direct evidence of an increase of sickness for the reason stated by Mr. Somerville.

**Sale of Liquor to Young Persons.**—Lady Astor's bill, entitled Intoxicating Liquors (Sale to Persons Under Eighteen) Bill, will come up for second reading in the House of Commons on March 9th, when it will have first place. The measure proposes to prohibit the sale of any intoxicants to anyone under 18. As the law stands now, any child over 14 may buy intoxicants, but none can buy spirit until reaching 16 years of age. It is claimed that this bill is not essentially a temperance measure, but is promoted with the support of teachers in the interest of adolescents.

**Vaccination of Army Recruits.**—Lieut.-Colonel Guinness, in answer to Mr. Leech on February 21st, said that no recruit for the Regular Army was enlisted unless he signed the attestation paper, in which he undertook the obligation to be vaccinated or revaccinated. If a recruit subsequently refused to fulfil the obligation, it had always been the practice to discharge him without gratuity on the ground that "his services are no longer required." This system had not been changed, but the wording of the regulations had been amended, and the cause of discharge was now more exactly defined as "refusal on the part of a recruit to carry out the agreement to be vaccinated or revaccinated entered into on enlistment." The rule applied to all regular recruits without exception, but not to recruits for the Territorial Army.

**Vaccination in Germany.**—Mr. Sullivan asked a question, on February 22nd, as to a statement in a pamphlet issued by the Ministry of Health which attributed the compulsory revaccination laws which existed in Prussia since 1834 to the year 1874, that being the year in which the Prussian laws were re-enacted for the new German Empire, thus concealing the fact of a serious outbreak of small-pox under conditions of strict vaccination. Sir William Joynson-Hicks said that the statement in the pamphlet was correct. The Prussian law of 1834 referred only to soldiers in the Prussian army. Compulsory revaccination for the civil population in Prussia and the rest of the German Empire was first enacted in 1874. There was, therefore, no ground for suggesting that the pamphlet should be withdrawn.

**Vaccination Deaths.**—Sir W. Joynson-Hicks stated, on February 26th, in reply to Mr. Snowden, that during the year 1921 "vaccination" was mentioned on seven certificates of death and "general vaccination" on one. They were classified as follows: 3 to vaccination, 3 to erysipelas, 2 to purulent infection, septicæmia. The eight cases were all of children under 1 year.

## NOVA ET VETERA.

### THE FOURTH OF MARCH: A DOLEFUL ANNIVERSARY.

THE Christian Calendar, as it used to be observed, was a chronicle of joy. Though the commemorations were usually of a death, the attention of the faithful was directed to the triumph of the soul rather than to the trials and sufferings of the body. Thus each succeeding day was meant to be a fresh link in a glad chain whereby the wide world everywhere was bound around the feet of God. It was this aspect of the celebrations as much as a different theology that constrained the Puritan to their abolition. It was this, too, which preserved the few that remain to an unbelieving generation, which observes them as holidays and cares not to remember that they were also meant to be holy days. But the power of the Puritan is past, and rule is now divided between the Hedonist and the Pessimist. Should the last named ever come into his kingdom we may expect a new calendar, a calendar of calamities, in which each day will be a fresh stimulus to the remembrance of past and present evils. In such a mournful menology the fourth of March must hold a bad pre-eminence if, as many are convinced, it is the anniversary of the first appearance of syphilis in Europe. But that little word "if" conceals a sea of troubles, for the literature upon the origin of this disease is immense, very animated, not to say venomous. "Bone Deus," wrote one of the disputants in 1783, "quot sunt illico factae medicorum concertationes, disputationes, discordiae!" Happily to-day the sounds of strife are stilled and one may venture, with all submission unto maturer discernments, to outline the argument for the fourth of March.

Whatever judgement may be passed upon the alleged proof of the existence of syphilis in prehistoric man, there can be no doubt that to the practitioners at the end of the fifteenth century it was a new disease. Classical and mediaeval literature has been passed, as it were, through a fine sieve, but no unequivocal reference to it has been discovered. The medical lore of the past has been searched with zeal even greater, but in the result equally futile. Syphilis staggered the doctors of that day out of their medical catechism. In presence of the "Veneris monumenta nefandae" they recognized the "inextricabilis error" of the maze they had been treading, and found the thread that ultimately guided them into a new world untrammelled by authority. By the year 1500 the portent had appeared in every country of Europe. In the British Isles the first notice comes, curiously enough, from Aberdeen, where, on April 21st, 1497, the town council issued regulations "for the eschevin of the infirmitey cumm out of Franche and strang partis." Six months later, September 22nd, Edinburgh was forced to take measures "for the eschewing of the greit appearand danger . . . fra this contagious sickness callit the Grandgore." Both these documents agree with other early notices from Northern Europe in attributing the new disease to France.

In France various notices of earlier date are available, but the edict issued in Paris on March 6th, 1497, is of special interest because of its opening words:

"Pourceque en ceste ville de Paris y avoit plusieurs malades de certain maladie contagieuse nommee la grosse verole, qui pai deux ans en ça a eu grand cours en ce Roiaume, tant de ceste ville de Paris que d'autres lieux."

Without reading a too strict chronology into this document it is safe to say that the disease had not been evident to the public before March, 1495. We learn also from Lyons and elsewhere that the outbreak in the locality was due to the advent therein from Italy of soldiers suffering from it. Of the famous expedition of Charles VIII into Italy much has been written, but a few piquant phrases from Dr. Pangloss must suffice here:

"Personne n'ignore combien cette expédition fût inutile et brillante. Nos chevaliers y développèrent l'héroïsme le plus admirable et le plus infructueux. Ils prirent avec rapidité Milan, Florence, Rome, Naples et—la grosse verole. . . Ce fut à peu près l'unique fruit . . . d'une campagne si glorieuse."

A few dates will fix the sequence of events. Leaving Lyons with his army in August, 1494, Charles crossed the Alps on September 2nd, and after being laid up at Asti with an attack of small-pox he reached Rome on December 31st. He did not enter the kingdom of Naples, the direct object of

his enterprise, till February 22nd, 1495. The prize fell into his hands almost without a blow, but he only remained within the territory till May 20th, when his army began the homeward march. But he had been too successful, and this made all the Italian States his declared enemies. Had they been united his doom was sealed. As it was, he had to fight his way back, and even his great victory over the Venetians only enabled him to withdraw the army into France, which was reached in October. Meanwhile Naples had been lost as quickly as it had been gained. The few French troops were shut up within strongholds here and there, but had to surrender one after another, so that the last of them reached France early in 1496. As for syphilis, we have the records of two surgeons in the Venetian army who note its appearance at the time of the French retreat, while the French alleged that it first broke out among them when they were in Naples—that is to say, some time after February 20th, 1495.

So far we are on common ground. All are agreed as to the epidemic at Naples and as to the part the French army played in its spread through Italy into France and so to other countries. But what about the disease before February, 1495? The condition of Italy at that time was indeed deplorable. Fracastor has described it in poetic diction but with sober truth:

Ergo hanc per miseris terras Saturnus agebat  
Pestem atrox, nec saeva minus crudelis et ipse  
Miscebat Mavors, conjunctaque fata ferebat.  
Quippe lue hac nascente, putem simul omnia diras  
Eumenides cecinisse fera et crudelia nobis.  
Tartareos etiam barathro dira omnia ab imo  
Excivisse lacus, Stygiaque ab sede laborem,  
Pestemque, horribilemque famem, bellumque, necemque.

These lines are rendered as follows by Nahum Tato, afterwards Poet Laureate, who published a translation of Fracastor's poem in 1686:

From hence malicious Saturn's Force is known,  
From whose malignant Orb this Plague was thrown,  
To whom more cruel Mars assistance lent,  
And club'd his Influence to the dire Event:  
Nor could the malice of the Stars suffice,  
To make such execrable Mischief rise;  
For certainly e'er this Disease began,  
Through Hell's dark Courts the cursing Furies ran,  
Where to astonish Ghosts they did relate,  
In dreadful Songs, the Burthen of our Fate;  
The Stygian Pool did to the bottom rake,  
And from its Dregs the curst Ingredients take,  
Which scatter'd since through Europe wide and far,  
Bred Pestilence, and more consuming War.

If ever the dragon womb of Stygian darkness could beget a plague it was here. Little wonder that the spontaneous generation of syphilis found acceptance. But nowadays one must look for carriers or sporadic cases. The latter no doubt occurred, but were missed because they were sporadic. But whence came the infection to Italy? Benedictus offers a clue: "novus . . . morbus gallicus ad nos ex occidente—irrepsit." Does he refer to Spain? If so the path of infection was easy. A Spanish family ruled in Naples, and their relations with the mother country were intimate. Many Spaniards came to Italy in search of fame or fortune. One of these, Roderigo Borgia, was then seated on the papal throne. Thousands of Jews came thither on their expulsion from Spain in 1492, and they were joined in the immediately succeeding years by numbers of the Marani or cryptic Jews about whose conversion to Catholicism Ferdinand was doubtful. Opportunities for infection from Spain were therefore abundant.

But neither the Jews nor the Moors of Spain are noted as being affected by diseases different from those of their Christian neighbours. One direct piece of evidence we have, however. It is from Roderigo Diaz, who practised for many years in Barcelona and was there when Columbus and his companions after the first voyage to America came to pay homage to their sovereigns (April, 1493). He explicitly states that some of the sailors were affected by the new disease, and that it rapidly spread through the city and thence to Europe. He also adds that the sailors were infected by the natives in Hispaniola. Oviedo is no less emphatic. He was at the Court at Barcelona when Columbus arrived; he had conversations with him then and in after years; he knew personally many of those who accompanied Columbus on his voyages. In 1515 he went to Hispaniola as a government official, had visual corroboration of the presence and frequency of the disease there, and obtained from the natives confirmation of its antiquity among them. Oviedo had no medical training, but the subject was one in which he was much

interested, and he took great pains to ascertain the truth. According to this story, therefore, syphilis accompanied the Spaniards on their first voyage home. They first touched land at Lisbon, where they rested for nine days, passing thereafter to Seville and thence overland to Barcelona. As they landed at Lisbon on Monday, March 4th, 1493, that day may rightly be regarded as "dies Europae fatalis." But if anyone feels too depressed on that sad anniversary he may gather some solace by recalling the event which marked the preceding day, for it was upon March 3rd, 1905, that Schaudinn discovered the spiral protozoon to which he gave the name of *Spirochaeta pallida*.

Fallopian, in speaking of America, said: "Inventum est certo pretiosissimum metallum, inde delata est copia. . . Sed est etiam adjuncta spui, et alio melli admista. Detulit enim Columbus tirremes Gallica lue refertas." And he was right. But if we robbed America of its precious metal in the past, we have suffered sorely for the wrong. And the end is not yet, since the debt of gold we are burdened to repay at compound interest for many a year to come. The philosophic mind, however, might be tempted to regard this material loss as clear gain if only the Western world would recall from us what it originally bestowed as a spontaneous gift.

G. M. C.

## England and Wales.

### THE NEW SPIRIT IN PSYCHIATRY.

We have received from Dr. H. Dove Cormac, medical superintendent of the Cheshire County Mental Hospital, a copy of the report by Dr. C. Hubert Bond, Commissioner of the Board of Control, on his annual visit of inspection to that institution. The concluding sentences of the report are as follows: "The fact that a substantial pecuniary recognition is available here to any member of the medical staff who obtains a diploma in Psycho-logical Medicine prompts me to express the hope that it will be found possible to bring into activity a school in that subject, which it is understood that the authorities at Manchester University are willing to arrange. I also desire to express my conviction that, could it be found feasible to establish at a general hospital out-patient treatment, to be undertaken by the medical officers here, for mental cases sent by their family doctor, much advantage would be derived thereby, especially towards the prevention and cutting short of cases of mental illness arising in the area served by this hospital."

### THE CANCER HOSPITAL, LONDON.

An appeal for funds is being made on behalf of the Cancer Hospital (Free), Fulham Road, London, to commemorate the services to the hospital of the late Sir Charles Ryall. The present operating theatre is no longer adequate for its purpose, and it has been resolved to double the present accommodation. The erection of this new unit will involve other alterations, as existing structures will have to be modified. During the last few years the work of the out-patient department of the hospital has greatly increased and new departments have been opened for medical, dental, and laryngological cases, while now deep-therapy apparatus has been installed in the electrical and radio-therapeutic department. A rearrangement of the out-patient department is, therefore, also necessary in order to make better use of the space available. In 1910 a research institute was erected, but the research work has been limited by the amount which the committee could appropriate for the purpose. It is hoped that a sufficient sum will be raised to provide for the endowment of research, as well as to pay for the structural alterations contemplated in the hospital.

### CENTRAL MIDWIVES BOARD.

A meeting of the Central Midwives Board for England and Wales was held on February 23rd, Sir Francis Champneys presiding. Letters were read from the respective bodies informing the Board of the re-election of Sir Francis Champneys, Mr. Leonard Henry West, Mr. John Shields Fairbairn, Mr. Charles Sangster, and Dr. Lyster as their representatives on the Board for the ensuing year. Letters from the Hampshire and Surrey County Councils were considered, and it was agreed to inform the clerks of these councils that the Board does not see its way to prohibit the application or administration of any drugs other than a

simple aperient except under proper medical advice, and that it was the intention of the Board to convey this view by the resolution which it passed at its last meeting. A letter had been received from the London County Council with reference to the resolution as to the duty of a midwife to call in medical aid in any case of ruptured perineum which requires stitching passed at the last meeting of the Board, and drawing attention to a letter addressed to the council's medical officer by the Board, in 1918, upon which the council had based its practice of considering the question of a serious rupture upon its merits and not upon the fact that the perineum required to be sutured; also that the council now assumes that any case in which a midwife sutures a perineum should be treated as a case of negligence or misconduct and reported to the Board for decision. It was decided to inform the London County Council that the circumstances under which the letter of 1918 was sent by the Board are no longer in existence and that the local authority should find a *prima facie* case whenever, in its opinion, the judgement of the Board is required.

A letter was considered from the Medical Secretary of the British Medical Association stating that the Council of the Association is of opinion that midwives should not administer anaesthetics except when they are acting under the direct personal supervision of the doctor in charge of the case, and expressing the hope that the Board will give the matter its serious consideration. It was agreed to inform the British Medical Association that the Board is in agreement with the view expressed in the letter, and that for special reasons only no action was taken in the case to which reference was made.

### SUNDERLAND EYE INFIRMARY.

At the annual meeting of the Court of Governors of the Sunderland Eye Infirmary the chairman, Mr. G. O. White, said that there had been a decrease of 54 in the number of cases treated in the institution during the past year, but the number of attendances had increased by 2,515, the total amounting to over 49,000; the number of patients admitted into the infirmary had also increased. There was, he believed for the first time, a deficit of £195 on the year's working, but trade had been very bad. The chairman then made the presentation of a gold watch to Dr. Boyd Cunningham, in recognition of his able and generous services to the institution as honorary surgeon and senior surgeon; it was now thirteen years, he said, since Dr. Cunningham came to the institution, and the work he had done had been most valuable.

## Scotland.

### EDINBURGH UNIVERSITY WAR MEMORIAL.

The Earl of Balfour, as Chancellor of the University, last week unveiled the memorial to the students and graduates of the University who fell in the great war. The memorial, which bears over one thousand names, consists of a series of handsome bronze panels let into the wall on the west side of the quadrangle, under the portico where formerly stood the statue of Sir David Brewster, which has now been removed. Above the memorial are sculptured the words, "*Vivere nos doceant qui didicere mori*," and, as the Chancellor said in his brief but eloquent address, "We cannot estimate our loss, but we have lost men who would have been great statesmen, great poets, great writers, great thinkers, leaders in science, leaders in religion, leaders in all social effort." Laurel wreaths and other floral tributes were laid at the base of the memorial by the Principal of the University, the President of the Students' Representative Council, and by representatives of the French, Serbian, and Polish students. A striking incident in the ceremony was the sounding of the "Last Post" by buglers placed out of sight in one of the stone galleries at a corner of the quadrangle; the sound dominated the whole quadrangle from above and was echoed from the surrounding walls.

### ROYAL MEDICAL SOCIETY DINNER.

The annual dinner of the Royal Medical Society took place on February 20th, the guest of the evening being Sir Humphry Rolleston, K.C.B., M.D., LL.D., President of the Royal College of Physicians of London. The dinner was held in the Hall of the Royal College of Physicians, and the company numbered about one hundred, including the Principal of the University, the President of the Edinburgh College of

Physicians, the Vice-President of the College of Surgeons, Vice-Admiral Sir John F. E. Green, Lord Murray, Lord Alness, the Deputy Director of Medical Services, the President of the Royal Faculty of Physicians and Surgeons of Glasgow, Professor Robertson, Professor Cushny, Professor Torrey, and Sir Norman Walker. The Chairman, in proposing the health of the guest of the evening, mentioned that 115 years ago the Society had honoured a very distinguished ancestor of his, Sir Humphry Davy. Sir Humphry Rolleston replied, and also proposed the toast of "The Royal Medical Society." In his speech he recalled that the Society was the oldest medical society in the United Kingdom, having been founded in 1734 by six students meeting in a tavern. Of the six original students—George Clegborn, Cumming, Russel, Hamilton, Archibald Taylor, and James Kennedy—Clegborn served with the army in Minorca, and subsequently became professor of anatomy at Dublin; and Russel wrote a *Natural History of Aleppo*, and at a later period was chiefly instrumental in starting the Medical Society of London in 1773. These two men were typical of the Scottish character in spreading, like missionaries, all over the empire and world the lessons learnt in Edinburgh. Other toasts proposed were "The Edinburgh Medical School" and "Sister Professions." Dr. Pearce, of the Rockefeller Institute, in replying to the latter, acknowledged the references that had been made to sister societies in America. The Royal Medical Society has recently instituted the new office of honorary president, and has elected Dr. Byrom Bramwell to be the first honorary president.

#### DEVELOPMENT OF LEITH HOSPITAL.

At the annual meeting of subscribers to Leith Hospital reports regarding the past year's work were submitted and reference was made to the projected building of a new wing as the Leith War Memorial. During the year 1,634 in-patients and 11,548 out-patients had been treated, the present accommodation of the hospital being 100 beds. For the year the ordinary income had been £8,782, and the ordinary expenditure £12,258, but the deficit had been more than covered by a gift of £5,000. The general decrease in hospital costs is shown by the figures for the previous year, which were £7,200 and £11,000 respectively.

#### GLASGOW EYE INFIRMARY.

At the annual meeting of contributors to the funds of the Glasgow Eye Infirmary Sir Hector Cameron, who presided, said that it was a matter for gratification that the subscriptions showed no diminution notwithstanding the present financial and economic conditions. There was an excess in expenditure over income of £1,273, as against a credit balance last year of £1,385. A considerable amount of work on the buildings had, however, been carried out during the year, including the installation of a new central heating system at a cost of over £2,000.

## Ireland.

#### THE GOVERNOR OF NORTHERN IRELAND.

The Duke of Abercorn, the Governor of Northern Ireland, made his state entry into Belfast on February 26th. Among the outstanding events of the day was the presentation of addresses in the Ulster Hall from various bodies, including Queen's University, Belfast, the Ulster Medical Society, the Royal Victoria Hospital, Belfast, the Order of St. John, and the British Red Cross Society. The Governor has made the following medical and dental appointments to his household:—Honorary Physician: Dr. J. A. Lindsay, F.R.C.P., Professor of Medicine in Queen's University, Belfast. Honorary Surgeon: Mr. Thomas Sinclair, C.B., M.Ch., F.R.C.S., Professor of Surgery, Queen's College, Belfast. Honorary Dental Surgeon: Mr. Herbert Williams, Londonderry, Ex-President of the Irish Branch, British Dental Association.

#### IRISH PUBLIC HEALTH.

At a conference arranged by the Irish Nurses' Union held recently in the Mansion House, Dublin, the following resolution was unanimously passed:

That this meeting calls upon the Government to appoint a Ministry of Health and Public Welfare so that the very urgent needs of the community in regard to health services may be considered.

Miss Louie Bennett, president of the Nurses' Union, in proposing the resolution, said that since the Government had not

yet formed a Ministry of Health it was important and urgent that public opinion should be aroused in connexion with the present state of public health in this country. Mr. R. J. P. Mortished gave details of a nursing scheme which might be carried out under the proposed Ministry of Health.

Dr. R. J. Rowlette (medical representative on the Irish Public Health Council) agreed that the health of Ireland had been neglected by those who governed the country in the past, and by creating a Ministry of Fisheries and neglecting to create a Ministry of Health the country had shown that it paid more regard to the welfare of the fish in the seas round the Irish coast than to the health of the people on the soil of Ireland. At present, health administration in Ireland was a generation behind that in any other civilized country in the world. In the twenty-six counties of the Free State there was only one whole-time medical officer of health, whereas in Great Britain every county and every considerable town had its health officer. There was no field of preventive work more fruitful than the medical inspection of schools, but, although such inspection had been the law of the land since 1919, no county had yet put it into force. In many instances the school buildings were themselves a danger to the health of the children. As to housing, one-fourth of the tenement houses of Dublin were in 1914 declared, not merely unfit for human habitation, but incapable of being rendered fit. There had been no improvement since. As regards reform of the Poor Law there had been important changes in the past few years, but they had been incomplete and not without fault. The concentration of all hospital treatment into one centre in each county brought great dangers to the sick, and district hospitals could not be dispensed with. He hoped the nurses would demand a national nursing service, just as the medical profession demanded a national medical service. He thought it better at the commencement to work to educate the public to the need of reform in health matters than to put forward partial and incomplete schemes in detail.

Dr. T. Hennessy, Irish Medical Secretary of the British Medical Association, said the truism that prevention is better than cure was fairly well appreciated in most countries if judged by the measures taken to give it effect. In Ireland, however, it would appear to be even scarcely enunciated.

It is true, he continued, that we have Public Health Acts in Ireland which, though somewhat ancient, would have served in their time useful purposes if efficiently administered. Public Health Acts, like other Acts of Parliament, require money for their administration. Public health measures are, in many instances, very unpopular with the public. They restrict the liberty and movements of people who have the misfortune to contract infectious and contagious diseases. For instance, there are parents who send their children to school for the twofold purpose of (1) having them educated, and (2) securing quietness in the home as the result of their absence. It is on occasions necessary in the interests of public health that school children, either suffering or convalescing from infectious diseases, should be kept at home so that they would not convey their diseases to other children. There are parents, however, who will tell a doctor that this is all nonsense and that their freedom and the freedom of their children should not be restricted for the benefit of other people. One would almost think they owed the children of other parents a grudge. Moreover, the same people, whether they are food producers or food retailers, will neither go to the trouble nor the expense to prevent the foods they offer for sale from becoming the vehicles oftentimes of fatal diseases to the consumers. Indeed they will treat it as an act to be strongly resented on the part of a medical practitioner who prevents them, in the interests of the public health, from disposing to the best advantage of their foodstuffs in the usual way.

Much of this could be prevented, or at least mitigated, even by the existing Public Health Acts in Ireland, only that the late Local Government Board seemed for some reason or another determined, whatever else might clash with the selfishness of certain people, that public health administration should not. In no other way can it be explained why the late Local Government Board never took any steps to have a whole-time county medical officer of health appointed to administer public health in Ireland, as was done in Great Britain. It will be readily understood, from what has been already said, the difficulties under which a medical attendant on a family was, in many instances, called upon to discharge also the duties of a medical officer of health. This was the unenviable position of almost every dispensary doctor in Ireland: he was called upon to discharge the dual duties of medical attendant and medical officer of health. Perhaps with the

view of keeping him inert the Local Government Board considered a salary of £15 to £20 a year quite sufficient. For this princely salary, as stated recently in the press, a dispensary doctor, in his capacity of medical officer of health, is solemnly expected to take care of the public health of some 7,000 human beings, and to prevent the occurrence and spread of typhus fever, diphtheria, and other virulent infectious diseases. If in the discharge of his duties he contracted, with fatal results, one of the deadly diseases the spread of which he was trying to combat, the fate of his widow and children was the workhouse—so far, at any rate, as the State was ready to come to the help of such cases. The obvious remedy was and is to appoint a whole-time county medical officer of health, who would be independent of private practice, and thus in a position to take the necessary steps, without any ill consequence to himself, to protect the health of the public.

Another Public Health Act which could have served very useful purposes is the Inspection of Cowsheds and Dairies. This Act had for its main objects the production of milk, butter, and cheese under good sanitary conditions. For the administration of this Act one official to a union was considered sufficient, and he may be a veterinary surgeon or he may be anybody—and he was invariably "anybody." The area of the district inspected by one official was generally some twenty-five miles in length by as many in breadth. For the work to be done the Local Government Board either approved or directed that a salary of £25 or £30 per annum should be paid. Such a salary would not cover the travelling expenses which would be necessary for an inspection lasting for fourteen days. Needless to say the inspection was of a more or less perfunctory character, and if it were meant to be anything else at the salary allowed, the Local Government Board alone could tell. Intentionally or unintentionally the Local Government Board took very certain measures that the Public Health Acts should be inoperative in Ireland. Apart from the health of the Irish people the Local Government Board did not, during its existence, even appreciate the commercial value of a national reputation for an up-to-date public health in a country like Ireland which exported so much of its food products. The part played by the late Local Government Board in Irish public health leaves very little reason to regret its demise. It must, however, be said that the medical department of the late Local Government Board was in no way responsible for the condition of affairs mentioned. The medical administrators, in late years, especially Sir Edward Coey Bigger, did an immense amount of very important public health work, but they could make no headway as the medical side of the Local Government Board was run as a mere side-show of little or no importance. This is the position of public health and preventive medicine in this country in 1923, which, on the whole, is only a little better than a hundred years ago. The immunity we enjoy to-day from the more virulent infectious diseases is entirely due to the medical practitioner. In his individual capacity he has been trying to do what the State neglected.

Drs. K. Lynn, W. M. Crofton, and J. P. Shanley also spoke in connexion with the means to be adopted for the prevention and treatment of tuberculosis, especially in children.

## Correspondence.

### EDINBURGH UNIVERSITY WAR MEMORIAL.

SIR,—The solemn ceremony which took place here on February 19th, when Lord Balfour, as Chancellor of the University, unveiled memorial tablets on which the names of nearly one thousand victims of the war are inscribed, is an event that will appeal to Edinburgh graduates all over the world. May I take this means of letting them know that it is still open to them to share in the commemoration? Subscriptions to complete the cost are required and will be welcomed from members of the University who have not yet subscribed. It is the desire of those who are responsible that the cost should be met by many gifts of small sums, so that the scattered sons and daughters of the University may feel that they have a part in this beautiful and appropriate mark of honour to our dead.—I am, etc.,

Edinburgh, Feb. 21st.

J. A. EWING,  
Principal and Vice-Chancellor.

### NEW REGULATIONS FOR THE D.P.H.

SIR,—The proposed new rules for Diplomas in Public Health which are criticized by the Committee of Management of the Examining Board in England of the Royal Colleges of Physicians and Surgeons have for their object the raising of the academic status of those who desire to enter the public

health service as a career. The fact that they make it increasingly difficult for members of the R.A.M.C. and possibly for those who take up medical practice abroad to obtain the diploma is not a sufficient reason for relaxing the stringency of the rules. The D.P.H. is essentially a civilian qualification, and is primarily intended for home practice; it is not a necessary adjunct to the medical equipment of a R.A.M.C. officer, for whom adequate instruction in matters of hygiene is provided in the army curriculum. For those who enter medical service abroad a more appropriate extra qualification is a Diploma in Tropical Medicine, as it is obvious that a course of instruction which is quite applicable to conditions obtaining in the industrial centres and rural districts in the homeland would not necessarily be of equal service under vastly different conditions of colonial life.

It is to be hoped that the General Medical Council will not be influenced by special pleading on behalf of a very limited section of prospective candidates for the D.P.H.—I am, etc.,

JAMES J. PATERSON, M.D. Lond., B.Sc., D.P.H.

Maidenhead, Feb. 24th.

### ENDOCRINE ACTIVITY AND FOETAL LIFE.

SIR,—For some time I have been engaged in the investigation of an abortive type of cattle offspring which, besides showing certain features characteristic of achondroplasia in the human species, displays certain abnormalities of the endocrine system which suggest another issue of medical interest—namely, the time at which the ductless glands begin to function.

It is well known that " " tissue " is differentiated long before " " probability that the adrenal medulla is " " functional at an early stage in ontogeny. In medical literature one finds not unfrequent references to foetal cretinism, implying that this is also true of the thyroid. But I am not aware that this view has been tested by critical experimentation. Recently I have been able to compare the action of thyroid from 2-months-old and full-time foetal calves by its specific power (Jensen and others) to induce metamorphosis in the Axolotl form of the Mexican salamander, a variety which in nature permanently retains and breeds in the larval condition. The results were negative in the former and positive in the latter case, showing that the foetal thyroid certainly begins to manufacture its active secretion before birth actually takes place. In view of the paucity of evidence on this question, it is proposed to extend the inquiry by quantitative experiments with thyroid from foetuses at different ages, at the same time testing the activity of post-pituitary extracts from the foetal animal by the extremely facile and delicate response evoked by their action in the frog's skin. (Hogben and Winton, 1922.)

The question of endocrine activity in foetal life is of such importance in connexion with the etiology of developmental disorders that I trust in the meantime to benefit by suggestions from any of your readers who have data, direct or clinical, bearing on the time at which the endocrine organs of the foetus become independently operative.—I am, etc.,

F. A. E. CREW, M.D., D.Sc., F.R.S.E.,

Director.

Animal Breeding Research Department,  
The University, Edinburgh, Feb. 22th.

### PRIMARY UNION AFTER OPERATION FOR SUPPURATIVE APPENDICITIS.

SIR,—As one who has interested himself in this subject for some time (vide BRITISH MEDICAL JOURNAL, October 28th, 1911, *ibid.*, May 25th, 1912), I am in complete accord with Mr. Robert G. Riddell when, in primary closure of the wound in suppurative appendicitis, he states (BRITISH MEDICAL JOURNAL, 1923, p. 322) that "the tissues of the abdominal wall have not the same capability as the peritoneum of dealing with infective organisms."

In a series of eighty-five cases of acute appendicitis published by me (*Glasgow Medical Journal*, September, 1913)—two and a half years' cases—eighty were closed primarily. Those cases only were included in the list in which (1) the appendix was gangrenous, either in whole or in part, with local or general infection of the peritoneum, and (2) those cases in which there was a localized abscess completely shut off from the general peritoneal cavity, the appendix being the *fons et origo mali* and in varying degree of inflammatory destruction. No case was included in the list which did not come under one or other of these groups. Fifty-seven out of the eighty-five cases healed primarily. In twenty-seven there was some

infection of the wound. Seven cases died—in one case death occurred six hours after admission; in every case save one death was due to general peritonitis. No drainage will arrest a streptococcal infection of the peritoneum. Like Mr. Riddell I tried to obtain primary union by protecting the wound against infection from the already infected peritoneum, and agree with him that it is necessary to use some antiseptic to the wound in spite of the damage done to the cells by the chemical. What I found most satisfactory to begin with was iodoform emulsion, 10 per cent., poured into the wound before the peritoneum was opened and again after the peritoneum was closed. This was combined with a stock vaccine of *Bacillus coli* given subcutaneously. For some time, however, I have abandoned this in favour of iodine, 4 per cent. in rectified spirit, applied to the wound in the same manner as was the iodoform emulsion, with excellent results.

I congratulate Mr. Riddell on obtaining seven consecutive cases, with one exception, of primary union following the use of flavine; personally, however, I do not like the employment of an aqueous solution of any antiseptic—Mr. Riddell flushed the wound with a solution of flavine, 1 in 1,000—because I believe that all wounds heal better when kept dry, and the rectified spirit in the iodine is an important factor in this connexion.

I am still of opinion that the vast majority of these cases of suppurative appendicitis can be treated by primary closure of the abdominal wound, provided the focus of infection is removed and the appendix stump effectively closed. No case of appendicitis, however, should be allowed to go to the stage of gangrene, of perforation, or of abscess, but that time is evidently not yet.—I am, etc.,

Bournemouth, Feb. 25th.

J. GRANT ANDREW.

#### HOSPITAL POLICY.

SIR.—The discussion on this policy has been continued under every head except one—namely, the development and improvement of the profession of medicine and surgery. My opinion is that before another twenty-five years the hospitals, as on the Continent and, I believe, in some of our colonies, will become State owned. The devices which are now being tried to raise funds will soon become stale, will cease to appeal to the public, and funds will become exhausted.

If we face the inevitable frankly and at the same time suggest a way out of the present difficulties, we shall get a sympathetic hearing from Government and public. The remedy is to institute a State qualification on a par with a good university degree, and make this the sole right to practise. Inferior qualifications would be automatically abolished, but the professors of these institutions need not starve—they could still continue as teachers.

The State would furnish the necessary buildings and equipment in each locality; the staffs would consist of local men, all State examined and all competent. Each man could pursue a specialty, first as a junior, and after some few years as a full surgeon or physician.

Private practice would not necessarily be debarred. The rich, if they chose, could consult any doctor privately and make adequate arrangements to be treated at home if they wished. The ordinary run of humanity, and especially the middle class, would be in a much better position than they are now. People would be as well treated under such conditions, for the medical profession would not cease to maintain the high standard which it has hitherto held. Why did we, until quite recently, so slavishly bow down to German and Austrian medical opinion? In those countries the hospitals are all State owned.

Collapse of the present system is inevitable; let us, for once at least, anticipate events, and give to the State a workable method of dealing with these problems.—I am, etc.,

Fulham, S.W., Feb. 19th.

JOHN FLETCHER.

SIR.—By a careless oversight I omitted from the letter appearing under this heading on page 353 of your last issue the section intended to answer the question: "What about having consultations and treatment provided at the out-patient department of a voluntary hospital for members of a contributory scheme, under which there is a stated or implied return required?"

These persons, being insured, are not objects for charity, and therefore the procedure suggested should be somewhat as follows:

(a) All services of a consultative nature should be given by the consultant either at his own address or at the patient's home, in so

far as it is possible and consistent with the best interests of the patient. In large towns at clinics organized and controlled by the medical profession the fee should be paid from the contributory fund.

(b) The contributor should be free to choose the consultant from a list prepared by the governing body of the British Medical Association covering the area of the scheme, such list being prepared in accordance with paragraph 31 (d) of the Memorandum on the Hospital Policy of the Association (SUPPLEMENT, BRITISH MEDICAL JOURNAL, October 7th, 1922, p. 134). The list should not be limited to members of the staffs of hospitals.

(c) All consultations should be arranged by the private medical attendant.

(d) Treatment at an out-patient department of a hospital should be given only where no other arrangements are practicable; or in case of emergency.

As is well known, the greatest abuse in the past has been through the out-patient departments—abuse of charitable funds and abuse of the charity of doctors. If not carefully watched the powerful influences interesting themselves in the forty to fifty schemes now floated in England will further develop this abuse. There is a popular fallacy that none of the specialized medical services can be obtained apart from a voluntary hospital. It is up to our profession to disabuse the public mind on this point by adopting a scheme under which the majority of such special services can be obtained elsewhere, promptly and in comfort for all concerned.

The premiums adequate for insurance can be well within the capacity of all. If it is kept in the forefront of all negotiations that these persons, having insured, are no longer objects for charity, whatever their individual financial position may be, it will become easy, when advising how to secure for them any special service, to turn one's mind in that direction in which one looks when making arrangements for a patient who will pay the fee out of his own pocket. The tendency to look to a hospital as the be-all and end-all is becoming accentuated.

May one venture to urge staffs of hospitals to approve the propositions outlined above and in the previous communication (p. 353), and to refuse to co-operate in any scheme which to all intents and purposes is dependent on the misappropriation of funds subscribed for the indigent poor and on the underselling of their own services, with the consequent deprivation of the means of livelihood of their professional colleagues who are competent to be on the staff for one or other of the special services required under these schemes? Is it not imperative on each one of us to consider seriously the position gradually arising as the result of present-day attempts by the State and by private enterprise to organize and control medicine? Will it be found eventually to be for the good of the people—for the good of medicine?—I am, etc.,

Hove, Feb. 24th.

E. ROWLAND FOTHERGILL.

#### SMALL-POX AND VACCINATION.

SIR.—Dr. M. P. Ravenel (February 24th, p. 351) says that I have misrepresented the attitude of Dr. Herman Biggs towards vaccination. If I have done so I hasten to express my regret. I am glad that I guarded myself to some extent by saying "as I understand." It is satisfactory, however, to find that the main facts of the case upon which I based my argument are not disputed. I did not think that they could be, as I received them direct from a medical officer who had held an important position in the Health Service of New York State at the time the repeal of the compulsory vaccination law came about, and who assured me that he was thoroughly conversant with the circumstances. I made a written note of what he told me at the time.

We now have it, in Dr. Biggs's own words, that it was on account of serious injury to health (eleven deaths from tetanus arising as a sequel to vaccination) that the vaccination law in the State of New York was repealed. Therefore it is difficult to follow Dr. Ravenel when he states, at the end of his letter: "He [Dr. Biggs] did not at that time believe, nor does he now believe, that vaccination in childhood produces any injury to the health of the child." I would suggest that perhaps Dr. Ravenel is himself misrepresenting the views of Dr. Biggs. Of course, Dr. Ravenel may reply that it was not vaccination but the tetanus which followed that was to blame, just as other untoward sequelae are so often explained away as being due not to vaccination but to sepsis. The dangers of most operations can be "explained away" by the same method of reasoning.

However that may be, I think we may assume that Dr. Biggs could not have believed that any very serious results

would follow from the repeal of the compulsory law or he would hardly have consented thereto. That is all the inference I wish to draw.—I am, etc.,

Leicester, Feb. 21th.

C. KILLICK MILLARD.

#### PENAL DISCIPLINE.

SIR,—Since Sir Wemyss Grant-Wilson has come at me (February 17th) with fresh matter, and has now made me responsible for a more gentle instrument of restraint than any known to me, may I briefly remind him that, whether the facts are given to the "general reader" by the Prison Commissioners, or through him, or me, or anyone else, "put in irons" is put in irons. We may possess, in handcuffs, an effective, temporary, life-saving apparatus, but its use will not absolve us from blame, if, by our system, we have first endangered the life which we subsequently save in that way. That is the point in my argument which Sir Wemyss has missed.

No reasonable being is, I think, likely to pass "hasty and unmerited criticism" on officers for doing their duty. Nothing in my book applies to them; therefore I should not consider that "speaking for" them would necessarily be doing them a service. "We"—not "they"—are responsible for the forms in which our penal discipline develops. It is for us, not for them, to realize first what is amiss. As this correspondence is really outside any matters contained in my book, I hope Sir Wemyss will agree with me that it may suitably stop at this point.—I am, etc.,

Zürich, Feb. 21st.

MARY GORDON.

#### THE DESTRUCTION OF HUNTER'S NOTES.

SIR,—I should like to say a word relative to the observation made by Sir John Bland Sutton in his Hunterian oration appearing in the BRITISH MEDICAL JOURNAL (February 17th)—namely, that the transcripts made by William Clift from some of Hunter's notes were afterwards destroyed by Everard Home. Now I remember my grandmother, Home's daughter, very well, and she always declared that her father never destroyed any of Hunter's manuscripts, but that a secretary or steward of Hunter's, having a personal spite against Home, in a fit of jealousy burnt many of Hunter's papers and laid the blame on Home! I remember her speaking of this man with the greatest loathing.—I am, etc.,

Scarborough, Feb. 22nd.

BERNARD HALE WOODYATT.

### Obituary.

CONSTANCE E. LONG, L.S.A., M.D.BRUX.,  
London.

We regret to announce that Dr. Constance Ellen Long of London died in New York on February 16th from pneumonia. She was born in Reading, and studied at the London School of Medicine for Women, taking the L.S.A. in 1896 and the degree of M.D.Brux. in the same year. She practised in London, and was formerly clinical assistant at the Royal Free Hospital and the New Hospital for Women, and medical officer to Dr. Barnardo's Home, Hawkhurst. She had held the office of president of the Association of Registered Medical Women, and represented the Medical Women's Federation on the Insurance Acts Committee from 1911 to 1914. Dr. Long was one of the earliest exponents in this country of the school of psychology that derived from Professor Jung of Zürich, and edited a volume entitled *Collected Papers on Analytical Psychology*, which included translations of many of Jung's articles. She wrote several papers on psycho-analysis and allied subjects, and a number of her contributions were published in a book, in 1920, with the title of *The Psychology of Phantasy*. She had been in indifferent health for some time, and had been making a prolonged visit to the United States as the guest of her friend and colleague Dr. Beatrice Hinkle of New York.

Dr. H. CRICHTON MILLER writes: By the death of Dr. Constance Long the profession loses a notable pioneer and a somewhat remarkable figure. She was best known as the first exponent in this country of the analytical views of Jung and the Zürich school. Just ten years ago she brought to England the first restatement of psycho-analysis, which had hitherto been practised only on strictly Freudian lines. As the editor of the English translations of Jung's books, her name soon became widely known. By her original papers,

by her lectures, and by her book *The Psychology of Phantasy*, she enhanced this reputation. During her seven years of general practice she not only built up a very valuable connexion, but she established a surgical nursing home that possessed many features well worth perpetuating. In these years she learned to recognize the frequency with which the functional factor enters into common complaints, and this brought her to the study of suggestion. Under the influence of Dr. Lloyd Tuckey she became a successful practitioner of hypnotic suggestion, and in 1912 she contributed to the discussion on insomnia at the Annual Meeting of the British Medical Association. But she remained unsatisfied by suggestive therapeutics, as was bound to be the case with anyone so bent on progress. Thus she came to the analytical phase of her life which was its culmination. Such was the road by which Dr. Long arrived at specialization in the teaching and practice of analytical psychology. Those who know her will agree that it was not the path of least resistance. She was not one of those for whom the new and the unconventional has a strong attraction. The intellectual interest of psychological work was not a compelling force with her, for she had not a specially critical mind, and its bent was practical rather than speculative. Indeed the analytical work she did was not cheaply achieved, but rather through indomitable and earnest application. Those who admired her most will agree that the driving factors in her make-up were unflinching generosity and sincerity. Nobody could ever imagine that Dr. Long was acting from any ulterior or selfish motive. While she talked and wrote a great deal about that spiritual freedom which analytical treatment is intended to procure, her life showed forth much more evidently a selflessness attained in a much more old-fashioned school. Brought up as she had been in the tradition of middle-class and Nonconformist puritanism, she no doubt had many "complexes" to submit to analytical treatment; but she also had that heroic urge towards the "better-than-what-is" that made her contribution to her day such a notable one. During the twenty-six years of her professional career she found time to take a considerable share in work for the profession. She was President of the Association of Registered Medical Women, and at one time was a member of the Insurance Acts Committee of the British Medical Association. She helped to found the Psycho-Medical Society, and was at the time of her death a member of the committee of the Medical Section of the British Psychological Society. In all these offices her place will no doubt be filled; but her place will not readily be filled in the hearts of many friends and patients who had learned to appreciate her wisdom, her integrity, and her sympathy.

Dr. JAMES YOUNG writes of Dr. Long: By her death the profession loses one who strove always to further the interests of medical science, and who bravely fulfilled the arduous function of pioneer in its most difficult and exacting department—that of medical psychology. She will be mourned by all those, friends and patients alike, who knew her for what she was—a woman of kindly and sympathetic understanding, who maintained an untiring devotion to duty in the teeth of the adversities of ill health and of those incidental to all attempts to broaden the basis of knowledge in any branch of human thought.

WILLIAM PRIOR PURVIS, M.D., M.S., F.R.C.S.,

Senior Surgeon, Royal South Hants and Southampton Hospital.

Mr. W. P. Purvis, who died at his residence at Southampton on February 13th, was born at Belize, British Honduras, and received his medical education at St. Thomas's Hospital Medical School. He took the diplomas of M.R.C.S.Eng. and L.R.C.P.Lond. in 1891, graduated M.B.Lond. in 1892 with honours in medicine, obstetrics, and forensic medicine, B.S. in 1893, M.D. in 1894, and M.S. in 1896; he also became F.R.C.S.Eng. in 1894. After serving as house surgeon and house-physician at St. Thomas's Hospital he was appointed house-surgeon to the Royal South Hants and Southampton Hospital, subsequently becoming senior surgeon and surgeon in charge of the ear, nose, and throat department of the institution. He was also consulting surgeon to the Free Eye Hospital, the Fenwick Memorial Cottage Hospital, Lyndhurst, the Lymington Cottage and the Milford-on-Sea Cottage Hospitals. Mr. Purvis served with the Southampton Volunteer Ambulance Corps during the South African war, and on his return he together with Dr. R. E. Lauder, the present M.O.H. for Southampton, received the freedom of the borough of

Southampton in recognition of services. He took a prominent part in the school clinic work, and was well known socially in the district.

Dr. JOHN FREDK. BRISCOE writes:

The death of William Prior Purvis is mourned by the united profession in Southampton. He practised the art of surgery for upwards of twenty years in Southampton, specializing, too, in diseases of the ear and throat. Quick, keen, and accurate in diagnosis, he showed himself to advantage in the operating theatre. Nothing tired him in endeavouring to unravel the vagaries of anomalous cases. He was very exacting in the out-patient department, for his clinic was a model of perfection in its thoroughness. Mr. Purvis was very attentive to his poor patients, giving them the most thoughtful consideration. Formerly he was house-surgeon, and step by step for over twenty years he assisted materially in modelling the Royal South Hants and Southampton Hospital to a high state of efficiency. His patients were always carefully noted and detailed, and this tabulation was also noticeable in the out-patient department. Nay, his out-patient clinic was schemed on the lines of the teaching hospital, to the great advantage of the resident staff. As a warm supporter of the British Medical Association he filled all the important offices of the Southern Branch to its presidency. At the Divisional and other meetings Mr. Purvis introduced important clinical material for debate, and, not least, showed interesting surgical cases. Not only was the town of Southampton favoured by his skill and dexterity in the science and art of surgery, but Mr. Purvis was a good citizen. After the Boer war, in which he served, the freedom of the town was conferred upon him. Likewise Mr. Purvis realized the obligations of Freemasonry, and was past-master of the Southampton Lodge and of the Twelve Brothers. He was a past-president of the Southampton Medical Society and its treasurer, while the Southampton Public Medical Service received his valuable support as its chairman. Whatever he did was accomplished with all his might, and here he excelled in detail. He leaves a wife and four sons, one of whom is at Cambridge, and four daughters. Mr. Purvis was cremated, and his ashes were solemnly taken to the grave in Southampton cemetery on February 19th, followed by the whole profession of the town and neighbourhood; and with his confrères were numerous civil followers from all parts of the district.

PETER CALDWELL SMITH, C.B.E., M.A. GLASG., M.D.,  
C.M., D.P.H. CAMBR.,  
Lieutenant-Colonel R.A.M.C.(T.).

We record with great regret the death, on February 21st, of Dr. P. Caldwell Smith, medical officer of health for the metropolitan borough of Wandsworth. While travelling in a tramcar on the previous day he became suddenly unconscious. He was taken to the West London Hospital, where he died without regaining consciousness of cerebral apoplexy. He was due to retire on pension in a short time, and was looking forward to a period of leisure after many strenuous years, not only as a public health officer, but in active service during the war. He had only just returned from two months' leave of absence, which he had spent in Italy, and his anxiety to resume work no doubt hastened his end.

Peter Caldwell Smith was a native of Lancashire, where he was born in 1858, but of Scottish parentage. His father was the late James Smith, LL.D., who for many years was secretary of the Educational Institute of Scotland. Caldwell Smith had a very distinguished career at the Glasgow University, where he graduated M.A. in 1878, M.B., C.M. in 1881, and M.D. in 1884. In 1888 he obtained his D.P.H. at Cambridge. For a short time he was lecturer on hygiene at Anderson College Medical School, Glasgow. In 1893 he took up general practice in Wandsworth, and the following year was elected medical officer of health for the Wandsworth parish of the Wandsworth district board. When the five parishes, each with a separate medical officer of health, which constituted the Wandsworth district were formed into the metropolitan borough of Wandsworth in 1901 he was elected medical officer of health for the new borough. He was a prominent member of the Society of Medical Officers of Health, acting on the council of the metropolitan branch of the society. In his presidential address he referred to the effect during half a century of the metropolitan main drainage on the mortality of the metropolis. He was not a prolific writer, contenting himself with taking part in discussions on public health

subjects at the meetings of various societies. He expressed himself clearly and to the point, and was always listened to as one having sound judgement and as a master of his craft. But Caldwell Smith will be held in remembrance, not alone as a distinguished medical officer of health, but as an enthusiastic member of the Territorial Force, which he joined soon after its formation. To him is largely due the success of the London Sanitary Companies. He was Sanitary Officer of the 2nd London Division when war broke out, and after serving abroad for a short time was appointed president of the London district travelling medical board. He was twice mentioned in dispatches and received the well earned honour of C.B.E.

Caldwell Smith will be remembered by his colleagues as one with decided opinions, but ever ready to adjust them to well reasoned argument. He could see the weak point in an opponent's case, but was too kindly disposed to take advantage of it by a smart or ill natured retort. To this trait is largely due the success of his public health administration in Wandsworth. He leaves to mourn their loss a widow a daughter, and two sons.

The death took place on January 29th of Dr. WALTER WILLIAM SINCLAIR of Ipswich. He was the son of the late Mr. T. S. Sinclair-Sparke, a solicitor, of Aberdeen and Banchoory, and received his medical education at Aberdeen University, where he graduated M.B., C.M. in 1891. After holding appointments at the Royal London Ophthalmic Hospital and the Birmingham and Midland Eye Hospital he settled in ophthalmic practice at Ipswich. He became a member of the honorary staff of the East Suffolk and Ipswich Hospital in 1896, and took charge of the ophthalmic department until 1920, when he was appointed consulting ophthalmic surgeon. During his time of active hospital duty Dr. Sinclair contributed a number of papers to the ophthalmological journals. He was an enthusiastic musician, and was prominently associated in the foundation of the Ipswich Orchestral Society; he also took an active interest in the Ipswich Amateur Opera Company and in the formation of the East Anglian Association of Musical Societies. He is survived by his widow and three daughters. A colleague writes: Dr. Sinclair established a great reputation as an ophthalmic surgeon in Ipswich and throughout the whole of East Anglia, a reputation which was thoroughly deserved. He was most thorough and conscientious in his examination of every patient and was a very skilful operator. His work at the East Suffolk Hospital did very much to enhance the reputation of that institution and was fully recognized by the Board of Management, who named the recently established ophthalmic wards the "Sinclair" wards to perpetuate his memory. He did much to encourage music in Ipswich. He originated the Ipswich Orchestral Society, and conducted in every concert from 1903 until 1915, when failing health compelled him to relinquish some of his activities. His success as a conductor was universally recognized and his enthusiasm inspired the society to reach the very high standard which it attained. He had a keen sense for literature and a highly cultivated and critical intellect. He was one of the most modest and unassuming of men, of a nature transparently honest and straightforward. He thought ill of no one, and no trouble was too much for him if he could do a service to a fellow creature.

We record with deep regret the death in Grenada, through a motor accident, of Dr. CONRAD J. ARTHUR, of the Grenada Medical Service. Dr. Arthur was the son of Canon Arthur, a native of Barbados, highly esteemed by all classes in Grenada. He took the diplomas of L.R.C.P., L.R.C.S. at Edinburgh in 1910, subsequently obtaining the degree of M.D. BRUX. He also spent some time at St. Thomas's before entering the Grenada Medical Service in 1911. In that service he had already made his mark, though a comparatively young man, for the introduction of the intensive treatment of yaws in 1919 was largely due to his zeal and initiative, and he also distinguished himself by his energetic prosecution of the local campaign against venereal disease. An active and able practitioner, a keen sportsman, and a good friend to the poor of the island, he will be missed by many, but by none more than his colleagues in the medical service, in whose interests he worked indefatigably during two years' tenure of office as Honorary Secretary of the Grenada Branch of the British Medical Association. To those who can appreciate the peculiar difficulties of the post during a period of

unceasing and unavailing efforts for reform, his loyal and courageous service to the profession will long stand as an example and encouragement. His loss at the moment, when the central body of the Association is entering upon the critical phase of the negotiations he conducted locally with marked ability and devotion, is an unlooked-for disaster.

## The Services.

### THE DIRECTOR-GENERAL, A.M.S.

It is officially announced that Major-General Sir William Boog Leishman, K.C.M.G., C.B., of the Army Medical Staff, has been appointed to succeed Sir John Goodwin, K.C.B., as Director General of the Army Medical Service, with effect from July 29th next, when the latter will vacate the appointment after five years' tenure. Sir William Leishman was born in Glasgow on November 6th, 1865, the son of the late Professor W. Leishman, and was educated at Westminster and at the University of Glasgow, where he graduated M.B. and C.M. in 1886. He entered the Army Medical Department, as it was then called, as surgeon, on July 27th, 1887, passing fifth into Netley. He became Major R.A.M.C. after twelve years' service, and on April 15th, 1905, was promoted to Brevet Lieutenant-Colonel, in recognition of his services and of the distinction he had obtained in original investigation and research. On December 11th, 1911, he became substantive Lieutenant-Colonel, on October 15th, 1912, Brevet Colonel, Colonel on March 1st, 1915, and Major-General on October 24th, 1918. Three years after obtaining his commission Captain Leishman (as he then was) went to India, where he served for six and a half years. He took part in the Waziristan expedition in 1894-95, and received the medal and clasp. He held the appointment of staff surgeon to Sir George Wolsley at Lahore, and did a considerable amount of work in bacteriology. His researches in connexion with kala-azar are well known. The parasite was first observed in 1900, but Leishman did not publish his discovery until 1903, when the same observation had been made by Lieut.-Colonel Charles Donovan, I.M.S., afterwards Professor of Pathology in the Madras Medical College. On return to England Sir William Leishman was posted to Netley, where he worked at bacteriology in Sir Almroth Wright's laboratory. He was Assistant Professor of Pathology at the Medical Staff College and R.A.M. College from February 1st, 1903, to January 31st, 1910; he was then appointed Professor of Pathology at the R.A.M. College, which post he held until January 31st, 1914. When war broke out he was War Office expert on tropical diseases on the Army Medical Advisory Board. He was sent to France in 1914 as Adviser in Pathology, which post he held until he was brought to England in April, 1918; he was appointed Director of Pathology at the War Office (June 1st, 1919). He was created a knight in 1909, C.B. in 1915, and K.C.M.G. in 1918; he was elected a Fellow of the Royal Society in 1910, and has received honorary degrees from the Universities of Glasgow and McGill. He was President of the Society of Tropical Medicine and Hygiene in 1912, and of the Section of Tropical Medicine at the Annual Meeting of the British Medical Association at Brighton in 1913.

## Universities and Colleges.

### UNIVERSITY OF OXFORD.

#### Appointment of Demonstrators.

THE Vice-Chancellor has approved the following appointments of Demonstrators for one year from Michaelmas term, 1922:  
*Department of Human Anatomy.*—M. H. MacKeith, B.M., M.A., W. W. Wagstaffe, B.M., M.A., Beatrice Blackwood, M.A.  
*Department of Physiology.*—H. M. Carleton, M.A., C. G. Douglas, B.Sc., D.M., F.R.S., E. G. T. Liddell, B.M., M.A. (for three years).  
*Department of Biochemistry.*—P. C. Raimont, B.A., M.R.C.S., L.R.C.P., G. L. Peskett, B.A.

### UNIVERSITY OF CAMBRIDGE.

THE Council of the Senate  
Right Hon. Sir T. Clifford  
Professor of Physics, to represent  
centenary celebrations of S  
on June 5th, 6th, and 7th.  
Professor F. Gowland Hopkins, Mr. G. E. Wherry, and Dr. L. Cobbett have been appointed members of the M.D. Degree Committee.

### UNIVERSITY OF LONDON.

At the January matriculation examination of the University of London 163 passed in the first division and 862 in the second division; 42 took a supplementary certificate for Latin.

The Graham Legacy Committee has reappointed Dr. V. R. Khanolkar to the Graham Scholarship in Pathology for two years from April 1st next. On this occasion the value of the scholarship is £300 a year. The reappointment was made on the recommendation of the School Committee of University College Hospital Medical School, at which Dr. Khanolkar's researches have been carried on during the past three years.

### UNIVERSITY OF BIRMINGHAM.

THE prize medals awarded by the University Clinical Board for the past session, together with the Arthur Foxwell memorial medals for 1921 and 1922, were distributed on February 19th by Principal Grant Robinson. The following were the recipients: Senior Medical Prize (gold medal) and Senior Surgical Prize (gold medal): H. S. Savage. Midwifery Prize (gold medal): P. Quinet. Junior Medical Prize (silver medal): S. H. Cookson. Junior Surgical Prize (silver medal): A. G. Taylor. Arthur Foxwell Memorial Gold Medals (for excellence in Clinical Medicine): 1921, A. S. Cookson; 1922, R. J. Gittins.

## Medical News.

A SPECIAL course in tuberculosis will be held at the Brompton Hospital for Consumption during the week beginning March 19th. A preliminary meeting will be held at 11.30 on that day; on other days the course will occupy practically the whole day—from 10.30 to 3 or 4 p.m. It will consist for the most part of demonstrations, and will include a few lectures. Full particulars may be obtained on application to the Secretary of the Hospital.

DR. J. H. SEQUEIRA will give a lecture on "Advances in the Treatment of Skin Disease by Light" on Thursday, March 8th, at 5 p.m., in the Anatomical Theatre of the London Hospital Medical College. The lecture will be open to senior students of the hospital and to post-graduates.

THE Prix de Carthage, a biennial prize founded in 1921 for scientific or historical work, has been awarded to Dr. Nicolle of the Pasteur Institute of Tunis for his investigations of typhus fever, kala-azar, trachoma, and Malta fever.

THE *Times* correspondent in Shanghai announces that the Associated British Chambers of Commerce there have passed a resolution welcoming the British Government's decision to devote the Boxer indemnity to purposes beneficial to Great Britain and China, and urging that the money be expended on the education of Chinese on British lines and the support of British medical work, educational and clinical, in China. The financial claims of Hong Kong University were pressed, and it was recommended that only a limited number of travelling scholarships to Great Britain should be granted.

THE next series of lectures to medical students and practitioners, arranged by the staff of Queen Charlotte's Lying-in Hospital, Marylebone Road, N.W., will be given on Thursdays at 5 p.m., commencing on March 15th, when Dr. C. Hubert Roberts will deal with rupture of the uterus, and terminate on April 19th, when Mr. Leonard Phillips will speak on the scope of Caesarean section.

THE sum of £48,487 was collected by the Hospital Sunday Fund last year as against £50,173 collected in 1921. During forty-nine years the sum collected by the Fund amounts to £1,835,711.

A DINNER to celebrate the twenty-fifth anniversary of the foundation of the Röntgen Society will be held on Thursday, March 15th, at the Hotel Cecil, Strand, London, W.C. Tickets, price 17s. 6d., including wine, may be obtained by members from the honorary treasurer, Mr. Geoffrey Pearce, 33, Newton Street, W.C.2.

A BELGIAN Pediatric Society has been founded at Brussels under the presidency of Professor Fèchère, and a congress of the Association of French-speaking Pediatricists will be held at Brussels in September under his chairmanship.

IN connexion with the course on children's diseases arranged by the Fellowship of Medicine at the Children's Clinic, Western General Dispensary, Cosway Street, N.W.1, Sir William Bayliss will deliver a lecture on the use of saline injections in the treatment of disease on Monday next, March 5th, at 5 p.m. Members of the medical profession are invited to attend.

A CHADWICK Public Lecture on the principles and practice of sanitary legislation will be given on Monday, March 12th, at 8 p.m., in the Inner Temple Hall, by Dr. Charles Potter, medical officer of health for the borough of St. Marylebone.

THE Council of the University of Paris had decided to confer the honorary degree of Doctor of Medicine on Professor W. W. Keen of Philadelphia and Professor Golgi of Pavia.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

The postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Attitology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Medisecra*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Practitus*, Dublin; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate*, Edinburgh; telephone, 4361, Central).

### QUERIES AND ANSWERS.

#### EXPIRATORY SPASM IN A CHILD.

SIR JAMES DUNDAS GRANT, in reply to "P." (BRITISH MEDICAL JOURNAL, February 24th, 1923, p. 358), suggests the possibility of the case of "expiratory spasm in a child" being one of infantile masturbation, as in a case referred to him as one of possible laryngeal disease. It was described by him in the BRITISH MEDICAL JOURNAL of April 27th, 1901, p. 1005, in a paper on "Traps and pitfalls in general and special practice," as follows:

"A curious instance of trap for the specialist was the case of a male child of about ten months old, brought to me on account of attacks of suffocation attributed to some obstruction in the throat. On inquiry I elicited that the attacks were characterized by evidences of intense nervous excitement culminating in a climax, followed by intense depression approaching collapse. This closely answered to the description of the orgasm given in Braun's work on diseases of children under the heading of infantile masturbation (*Selbst-Belebung*), that I ventured to diagnose it as such, the father confirming my opinion by the observation that during the attacks there was an obvious priapic condition. I found an elongated and tight prepuce and recommended circumcision, with, as I afterwards heard, the most satisfactory results."

#### INCOME TAX.

"C. J. H. A." asks: If on April 6th I return "Tom Jones £2" (booked the previous January), must I in the following January pay 10s. income tax, although Tom Jones has paid me nothing or a part only of the £2 due to me?

"We assume that "C. J. H. A." is making his returns on the basis that his "receipts" are his cash takings, plus the value of his book debts at March 31st, 1922, less the corresponding value at March 31st, 1921. If Tom Jones ultimately pays his £2 the result will be that "C. J. H. A." will pay tax before he receives payment of the debt; this is in accordance with the income tax statutes. To the extent to which the debt is considered irrecoverable it will disappear from the value of book debts outstanding at the end of a future year, and so go to reduce the "receipts" on which some future year's profits will be calculated—for example, suppose in 1922-23 Tom Jones pays nothing, and that the debt of £2 is written off as bad, then the "receipts" will, as a whole, be reduced by £2, because the closing value will be reduced by £2 as compared with the opening value.

### LETTERS, NOTES, ETC.

#### HICCUP.

DR. WILLIAM BRAMWELL (Liverpool) writes: Dr. H. J. Fardon's account (BRITISH MEDICAL JOURNAL, February 3rd, p. 220) of the cure of his hiccup by trying Mr. Money's remedy is, as he says, amusing; but this remedy, though "partaking of the nature of folklore," is, I think, capable of scientific explanation. Dr. Fardon tells us that he lay across the bed on his abdomen and, leaning over the edge with head downwards reaching almost to the floor, "managed to perform the feat of drinking water from the far side of the tumbler." The result being that, in spite of his scepticism, he was immediately cured of his hiccup. I agree with Dr. Fardon that the temporary cessation of breathing necessary to accomplish the performance was not the "item of cure." For an explanation we must look to the phrenic nerve, in this case, rather than to the vagus. The pressure exerted upon the abdominal contents by lying in such a position would in turn press upon the peripheral distribution of the phrenic nerve on the under or peritoneal surface of the downward jerk of the muscle, mechanical interference with the terminals of the nerve, check or by direct action on the nerve itself. And if so, pressure in their impulse and so inhibit the spasm. And if so, pressure in this position would be more effectual than pressure on the trunk of the nerve over the scalenus anticus muscle, a procedure which is not always successful and perhaps not without danger. Presure, too, on the ensiform cartilage, by relaxing the tension of the central tendon of the diaphragm, and thereby weakening the pull of the muscle on the cartilage, would also aid in inhibiting

the spasm. That pressure on the ensiform cartilage could bring about such a result will, I think, be shown by the following note of mine which appeared in the BRITISH MEDICAL JOURNAL of September 25th, 1915, in reply to a query by Dr. J. Numa Rat:

"In a case of persistent hiccup—a woman of about 35 years who

with the microscope the hiccup instantly ceased, but commenced again the moment the pressure was removed. Judging that the beneficial effect of the pressure was due to relaxation of some undue tension in the central tendon of the diaphragm, I made a pad of lint and bound it tightly on so as to exert firm pressure on the cartilage. The hiccup completely ceased so long as the pad remained in position, but returned whenever it was displaced. The patient wore the pad for two or three months with great benefit, but the hiccup finally returned so that no longer pressure over the cartilage would relieve it, and I lost sight of the case. I have had no opportunity of testing the efficacy of this method in other cases, but it is perhaps worth a trial in Dr. Rat's case if no osseous or other impediment exists in the cartilage."

I judge the primary success in this case was due to an unusually flexible ensiform cartilage yielding to a pressure sufficient to lessen the tension in the central tendon of the diaphragm, and that the ultimate failure was due to tuberculous irritation on the peritoneal surface of the muscle, and that the spasm in the later and more advanced stages of the disease, probably owing to a thickening and therefore less flexible tendon, refused to yield to the pressure on the cartilage.

Years ago a man was brought to Sir Patrick Dun's Hospital, Dublin, who had had incessant hiccup for several days. The hiccup continued during the whole night after his admission, but ceased on the following morning at the moment Professor Finny brought the students round the man's bed. The cure was instant and complete, and so far as I am aware the hiccup did not return. Dr. Finny said a few words about mental impressions in hiccup—surprise, shock, etc. I quote the incident as an example of the kind of case that would have brought great credit to the psychotherapist.

#### DETERMINATION OF SEX.

DR. F. HYDE MABERLY (London) writes: Dr. Reginald Maple's account (February 17th, p. 303) of the production of bull or female calves at will, provides strong confirmation of Dr. Rumley Dawson's theory of sex determination; which exactly parallels Dr. Maple's experience. In each case the ovulations produce alternately males and females.

#### "T.B."

DR. G. NORMAN MEACHEN (Westcliff-on-Sea) writes: Like Dr. Weatherhead, I have often been struck by the incongruous, not to say ignorant, use of the initials "T.B." to designate alike "tubercle," "tuberculosis" and "tuberculous," even in official documents. In my opinion, the simplest manner of abbreviating one word is to utilize the first or the first two of three letters. Thus, "T.O." should be sufficient to mean "Tuberculosis Officer," for the confusion with "Transport Officer" is one that is now hardly likely to arise. Personally, I always add "T.O." to my signature upon official documents—I never "T.B.O." Why should not the letter "T." alone be allowed to stand for tuberculosis and all that pertains to it? We have long been accustomed to "T.B." for tubercle bacilli, never "T.B.B."! If "B" must come into it at all, which it need not, let us have "Tub." A small committee, composed of representatives of the Royal Colleges and of the Ministries of Health and Pensions, might well be established to discuss the matter and prevent the continued perpetration of a ludicrous error.

#### A DISCLAIMER.

DR. EDW. JAS. DECK (London, W.) writes: It has been brought to my notice that a paragraph appeared in the 6.30 edition of the *Evening News* mentioning my name at some length in connexion with a method of treatment. I did not authorize or consent in any way to this publication, and it was published entirely without my knowledge.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 35, 37, 40, and 41 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 38 and 39.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 75.

### SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

An average line contains six words. All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive postage letters addressed either in initials or numbers.

## A British Medical Association Lecture ON PSYCHOLOGY AND MEDICINE.

DELIVERED TO THE BROMSGROVE AND DUDLEY DIVISIONS  
ON NOVEMBER 30TH, 1922,

BY

SIR FREDERICK W. MOTT, K.B.E., F.R.S., M.D.,  
LL.D., F.R.C.P.,

DIRECTOR OF THE PATHOLOGICAL LABORATORY OF THE LONDON COUNTY  
COUNCIL MENTAL HOSPITALS; CONSULTING PHYSICIAN  
TO CHARING CROSS HOSPITAL.

MR. PRESIDENT AND GENTLEMEN.—Permit me to thank you for the honour you have done me in asking me to address you on the subject of Mental Hygiene. It is especially a pleasant task for me, inasmuch as the City of Birmingham and the University have shown by their recent action how much they are interested in research into the causation, prevention, and remedial treatment of disorders and diseases of the mind. A Research Board will be established, and I have been asked to act as Honorary Director of Research and Lecturer at the University.

### BODY AND MIND.

The fundamental basis of mind is begotten with the body. There can be no mind without memory; there can be no memory without body. All psychic processes are subordinate to and dependent upon physiological processes.

No progress was possible in the advancement of our knowledge of mental disease until we had shaken off the spell of metaphysical speculation and the tradition of doctrine of the mind as an invisible intangible spirit with a separate existence in the body. We now generally recognize the brain as the seat of the psyche, but the functions of mind are dependent upon the whole body, and the harmonious interaction of all its parts.

The time-worn dictum, *Mens sana in corpore sano*, implies that if the body is healthy, then the mind is healthy, but there are numbers of people who suffer with bodily disease who nevertheless have a healthy mind; and again, there are numbers of people who have a disordered or diseased mind, but, so far as we can discover, have a healthy body—for example, various types of neuroses and psychoses, and of moral feeble-mindedness. But because we can by our present methods of investigation find no material cause for abnormality, it does not follow that subtle biochemical and biophysical changes, which are dependent upon inborn functional or bodily defects, are not there. Especially do I refer to the latest structures of evolutionary development—for example, the cerebral cortex.

### Pathological Processes in Relation to Body and Mind.

Pathological processes occurring in the brain may serve as a magnifying glass and help or point the way to the study of mind from a physiological point of view. At present we do not know the complex physiological processes underlying mental processes; but we do know that without oxygen, which is essential for all vital activities of the body, mental processes cease. The biophysical and biochemical processes are fundamentally the same in a simple reflex, the first term of a series, as in volition, which is the last. We now know how important are the internal secretions of the endocrine glands for vital activities of body and mind. Thus the adrenal acts as a reservoir of energenic substance which in emergency can be called upon automatically to discharge adrenalin into the circulation to excite through the sympathetic nerve the bodily reactions required for fight or flight in response to the emotions of fear and anger. The thyroid secretion, we know, is essential for the development of the organ of mind, for when this gland is absent cretinous idiocy is the result. If the cretin is fed upon thyroid the brain develops and with it the mind. Again, we know that mental energy is dependent upon thyro-iodin, for slowness of thought and action are associated with hypothyroidism and myxoedema. Administration of the gland cures the myxoedema and restores the mental energy.

There is definite clinico-anatomical evidence of the inseparability of body and mind. Thus mental deficiency is associated with, and proportional to, the arrest of development of the supragranular layer of pyramidal cells of the cerebral cortex. In dementia paralytica the dementia is proportional to the extent and degree of destruction of the

cortex cerebri which is due to the colonization of the *Spirochaeta pallida* in the brain; therefore, its cause being known, it is a preventable disease, and if preventable why not prevented? Every measure, whether educational, prophylactic, or remedial, which tends to diminish the spread of syphilis will tend to diminish enormously the proportion of cases admitted to asylums, hospitals, institutions for the blind, the deaf, and the dumb, and for mental deficiency due to congenital syphilis.

I do not see anything like the number of cases of congenital syphilis that I formerly did, and this diminution is the general opinion of physicians. If it had not been for the war I have no doubt there would have been a great fall in the incidence of syphilis among the population, but the war, unfortunately, has led to a great recrudescence of infection. Still, education, the Report of the Royal Commission, the change in attitude of the press regarding publicly, the introduction and knowledge of new and more efficient methods of diagnosis and treatment, will certainly diminish the number of infections. Again, the enormous number of men of all ranks in the army who were incapacitated for service at a critical period of the war has aroused public opinion in Britain and the colonies to the necessity of taking effective steps to mitigate this great peril. The campaign of two societies and the public interest aroused in the divergent views regarding the desirability of advocating self-disinfection for the civil population have also done much to awaken the interest of all classes of people. This public interest has stirred the Ministry of Health, and a Commission is at present sitting to investigate the best methods to be adopted for the prevention of the spread of venereal infection. Unfortunately the lowest stratum of society is incapable of appreciating the dangers of communicating infection to others, especially innocent women and children, by neglect of treatment. Yet there can be no doubt the establishment of free treatment centres throughout the country will, together with a wider distribution of knowledge of the causes of the spread of these diseases, and how they may be prevented and cured, lead to an increasing reduction of constitutional syphilis and all the various organic diseases of the nervous system for which it is directly responsible. Statistics indicate that about 10 per cent. of syphilized individuals subsequently die of organic disease of the nervous system, of which about 5 per cent. are general paralytics. A cure has not yet been found for general paralysis, and this makes it all the more imperative to adopt all measures which will lead to the prevention of infection.

### THE PSYCHO-NEUROSES, PSYCHOSES, AND MENTAL DEFICIENCIES.

But let us leave these acquired organic brain diseases and turn our attention to those psycho-neuroses, psychoses, and mental defects which we rightly regard as more or less due to inborn dispositions or defects. The last two classes—the insane and mentally deficient—are, owing to their antisocial tendencies or conduct, segregated for economy, with few exceptions, in huge institutions; these so-called mental hospitals have as a general rule no separate buildings for acute recoverable and convalescent cases. This mixing of acute, and possibly recoverable, cases with the chronic incurable is now being recognized as a thoroughly bad system, for it leads to a prevailing idea not only of hopelessness in the patients, but of helpless despair, even in those who have the care of them, of employing any medical aid towards assisting them to recover and preventing a relapse.

We may well turn, therefore, to what Francis Bacon said regarding supposed incurable diseases:

"A work therefore is wanting upon the cures of reputed incurable diseases, that physicians of eminence and resolution may be encouraged and excited to pursue this matter, as far as the nature of things will permit, since to pronounce disease incurable is to establish negligence and carelessness as it were, by a law, and screen ignorance from reproach."

### Psychology in Relation to the Study of Individual Characters.

Bacon thus advocated a treatise on the mind so that "better knowledge may lead to rules for the treatment of Mind."

"Wherefore out of these materials (which are surely rich and abundant) let a full and careful treatise be constructed. Not, however, that I would have their characters presented in Ethics, as we find them in history, or poetry, or even in common discourse, in the shape of complete individual portraits, but rather the several features and simple lineaments of which they are composed, and the various combinations and arrangements of which all characters whatever are made up, showing how many and of

what nature these are, and how connected and subordinated to one another, so that we may have a scientific and accurate dissection of minds and characters, and the secret dispositions of particular men may be revealed; and that from a knowledge thereof better rules may be framed for the treatment of the mind. And not only should the characters of dispositions which are impressed by nature be received into this treatise, but those also which are imposed upon the mind by sex, by region, by health and sickness, by beauty, deformity, and the like; and again those which are caused by fortune as sovereign prosperity and the like."—*De*

Bacon is here advocating a work upon character founded upon "dispositions impressed by nature" and those which are imposed upon the mind by nurture. Really this is a study of what an individual was born with and what happened after birth.

#### *Psychology in its Application to Medicine.*

The late Dr. Mercier, in the preface to his work on insanity, said that he had studied academic psychology as taught in the schools, and it may be remarked there were few who knew it better; yet he states that he found it as useful in practice as the cuneiform language. He asserted that it was disorders of conduct which should be studied.

We can only judge a man's mental state by what he says and what he does, and by the bodily expression of the emotions and passions, which often indicate the thoughts and secret dispositions of men more surely than speech, which, in many instances, is given to man to hide his thoughts.

Dr. Jung, in his remarkable work on analytical psychology, thus expresses his views upon the same subject:

"Modern experimental psychology is very far from being able to afford him any connected insight into the most vital psychic processes—that is not its aim. As far as possible it tries to isolate those simple elementary phenomena which border on the physiological, and then study them in an isolated state. It quite ignores the infinite variation and movement of the mental life of the individual, and, accordingly, its knowledge and its facts are so many isolated details, uninspired by any comprehensive idea capable of bringing them into co-ordination. Hence it comes about that the inquirer after the secrets of the human soul learns rather less than nothing from experimental psychology. He would be better advised to abandon exact science, take off his scholar's gown, say farewell to his study, and then, strong in manly courage, set out to wander through the world; alike through the horrors of prisons, lunatic asylums and through the dreary onlilying taverns, through brothels and . . . ant drawing-rooms, the Stock Exchange, . . . has, revival gatherings of strange religion. In his own person love and hate and every . . . would return laden with richer knowledge than his yard-long textbooks could ever have given him, and thus equipped he can indeed be a physician to his patients, for he understands the soul of man. He may be pardoned if his respect for the 'corner-stones' of experimental psychology is no longer very considerable. There is a great gulf fixed between what science calls 'psychology,' on the one hand; and what the practice of everyday life expects from psychology on the other."

The medical practitioner, much less the student of medicine, is unable to follow Jung's prescription to obtain the knowledge of psychology which will fit him best to understand human nature in all its varied characters and phases. Yet one must admit that this psychology of experience will be of infinitely more use to him than the academic psychology of the schools.

It may be asked, Where can we find the psychology of human character better portrayed than in the dramas of Shakespeare?—for as Schlegel, the great student and translator of Shakespeare into German, in his lectures on the drama says:

"Never perhaps was there so comprehensive a talent for the delineation of character as Shakespeare's. It not only groups the diversities of rank, sex, and age down to the dawns of infancy; and not only do the king and the beggar, the hero and the pick-pocket, the sage and the idiot, speak with equal truth." Then he goes on to say: "If Shakespeare deserves our admiration for his characters, he is equally deserving of it for his exhibition of the passions, taking this word in its widest signification as including every mental condition, every tone from indifference or peculiar mirth to the wildest rage and despair. He gives us the history of minds, he lays open to us in a single word a whole series of preceding conditions. His passions do not at first stand displayed to us in all their height, as in the case of so many tragic poets, who, in the language of Lessing, are thorough masters of the legal style in the language of Lessing, are thorough masters of the gradual of love. He paints, in a most inimitable manner, the gradual progress from the first origin. 'He gives,' as Lessing says, 'a living picture of all the most minute and secret artifices by which a feeling steals into our souls; of all the imperceptible advantages which it there gains, of all the other stratagems by which every other passion is made subservient to it, till it becomes the sole tyrant of our desires and our aversions.'

"Of all poets, perhaps, he alone has portrayed the mental diseases—melancholy, delirium, lunacy—with such inexpressible, and in every respect definite truth, that the physician may enrich his observations from them in the same manner as from real cases."

In Shakespeare we find the psychology of character revealed in all its aspects, the knowledge of which is so important for the success of a medical man.

Recently a valuable and philosophical work on character, by Mr. Hugh Elliot, has appeared; it is the first attempt which has been made (with the exception of Mr. Shand's *Foundations of Character*) to deal with the subject. He admits that the study of character is not and cannot for a long time be in a state which would justify the introduction of any name ending in "ology." It cannot begin to be a science until we can explain the cause of variations in characters. He remarks that wide knowledge is essential, and yet mere knowledge by itself avails little towards an understanding of character. Some of the most learned men in the world are as children in the comprehension of their fellow men; it is experience, as Jung has said, of the world from many and varied points of view that counts, combined with an intuitive sense.

#### *Intuitive Knowledge of Character.*

In all grades of society individuals exist who largely owe their success in life to an intuitive ability to read the motives and secret dispositions of men, and especially is this faculty of importance in the learned professions of Law, Medicine, and the Church. Most intelligent people in all ranks of life are more or less practical psychologists, for they judge of the conduct of their fellow men by analogy of their own thoughts and feelings which would be associated with that conduct; but although they may have practised this intuitive psychology all their life, they would be as surprised as the *bourgeois gentilhomme* in Molière's play was when told he had spoken prose all his life. By study and application this intuitive knowledge can be improved where it is present, and acquired where it is only feebly represented. Our object should be to develop this practical psychology.

#### THE TEACHING OF PSYCHOLOGY APPLIED TO MEDICINE.

I have been leading up to a thorny question, and that is, whether it is right to introduce any fresh instruction in the medical curriculum; the adage, *ars longa, vita brevis*, is too true for the medical student to-day. Yet I am constrained, owing to the experience of the war and its aftermath, to support a proposition—namely, that a short course on psychology in its application to medicine should follow a student's teaching in physiology—which I made to the Dean of the Faculty of Medicine of the Victoria University, Manchester, and which has been carried into effect. A letter to me from the Dean of the Medical Faculty states:

"Professor Pear gives four to six lectures in the second or third year as an introduction to psychology, in the course of lectures on the physiology of the nervous system, prior to the Second M.B. In the summer of the third year a short course of six or eight lectures is given on the psychology of human behaviour, and in the Lent Term of the fifth year a similar short course on morbid psychology as an introduction to the lectures on mental diseases, which the students take in the fifth summer."

Sir J. H. Parsons,<sup>1</sup> in a valuable address on medicine and psychology, points out that "the scientific study of the behaviour of human beings has been neglected by the medical profession." Medical students are compelled to spend years in acquiring a knowledge of the structure and functions of the human body, but are left with little or no instruction in the activities of the mind which the body subserves. No one would dream of teaching pathology without a preliminary course of physiology, yet every doctor is daily called upon to treat neuroses and psychoses with inadequate training. If medical students are taught psychology it should be by a more real and vital psychology based upon behavioural, biological, physiological, psycho-pathological, and sociological foundations, and the teacher should be a medical man who has acquired a thorough theoretical and practical knowledge of these subjects.

Formerly the subject-matter of psychology was almost entirely limited to what was called the content of "consciousness"—that is, to the thoughts and feelings of which we are fully conscious; its methods consisted of analysing the feelings and thoughts, and from them generalizing the feelings and thoughts of the human mind generally. This is the introspective method of analysis of mind; more and more

it is being realized that the behaviouristic method, applied primarily to animals and secondly to man, affords a far more sound approach to the vital problems awaiting solution. It must be admitted that introspective psychology is the final court of appeal, because, as Stout<sup>2</sup> says:

"All depends on accurate resolution of his own complex consciousness into its constituents and on recomposing these in such a way and in such proportions as to explain the nature and order of the signs which indicate to him the mental processes of others."

But consciousness is too narrow, for, owing to Freud and Jung's researches, the great importance of the unconscious in the study of mental processes has been demonstrated. This new psychology of psycho-analysis has created a wide-spread demand for instruction in psycho-pathology, but, as Sir J. H. Parsons truly says, "Freudism has been elevated into a cult, its truths have been overlaid with speculation, and the unconscious usurped an autonomy which it is scarcely likely to maintain."

#### THE INBORN FOUNDATIONS OF CHARACTER.

The dispositions impressed by nature are, in their order of evolution, species, sex, race, and family ancestry. Their ontogenesis is in great measure a recapitulation of their phylogenesis.

##### 1. Dispositions Impressed by Species.

"The life of a species is relatively continuous; from generation to generation it animates a fresh collection of individuals. They are the vessels of life, always being renewed, the old ones passing away, the new ones rising into existence; the life of the species is the only life that lasts. The lives of individuals are but passing phases of it." I may here remark that the grasping reflex of the newborn child is an illustration of a pre-organized neuro-muscular reflex mechanism reminiscent of its ape-like ancestry.

##### 2. Dispositions Impressed by Sex.

Human motives and conduct originate not only in the desires necessary for self-preservation but also in great measure from the depths of the passion engendered by the natural attraction of the sexes necessary for the procreation of the species.

In respect to the dispositions impressed by sex we know that every cell of the body possesses both male and female characters, but the male characters are dominant; Nature provides in the internal secretion of the interstitial gland of each sex a means of determining the specific characters of body and mind for either sex. Before birth and for some months after, the testis contains the interstitial cells; they, having fulfilled their function of fixing the male characters, disappear until the period of puberty, when they reappear. Observation and experiment show that the secretion of these cells determines the secondary physical and mental male sexual characters. In the female soon after birth Graafian follicles develop from the primordial follicles, and though these follicles do not undergo delisescence their formation leads to the development of the internal thecal cells, the secretion of which maintains the dominance of the female characters in the cells of the body. Removal of the ovaries in hen pullets shows that the male characters are dominant, for these birds thus operated upon grow up so as to be indistinguishable from cockerels, with spurs and comb; moreover, they behave as cockerels. Again, the effects in behaviour by numbers of experiments on animals and castration in man show the important influence of the sexual organs in the development of body and mind.

The specialization of the difference in sex characters becomes evident as the reproductive organs gradually mature after puberty. The various devices impressed by Nature, for example, display characteristics of each sex leading to attraction of the sexes. The evolution of the specific sex characters is all-important in the development of the sentiments and passions. The sex instinct is the great urge of adolescence; it is the *élan vital* of Bergson; or, as the Freudians term it, the "libido," found throughout organic nature. The *joie de vivre* accompanying it is poetically expressed by Romeo when the love of Juliet urges him to say:

"My bosom's lord sits lightly in his throne;  
And, all this day, an unaccustomed spirit  
Lifts me above the ground with cheerful thoughts."

We may contrast this with the soliloquy of the intellectual but melancholic, introspective Hamlet, who says:

"I have of late (but wherefore I know not) lost all my mirth, foregone all custom of exercises; and indeed it goes so heavily with my disposition that this goodly frame, the earth, seems to me a sterile promontory; this most excellent canopy, the air, look you, this brave o'erhanging firmament, this majestical roof fretted with golden fire, why it appears no other thing to me than a foul and pestilent congregation of vapours."

##### 3. Dispositions Impressed by Race.

Everyone knows the great influence race has upon character; and McDougall in a recent interesting work has shown how very little fundamental racial dispositions are influenced by environment. The great difficulty in determining whether racial characters can be modified by environment is that few races are pure; another difficulty is to find a pure race that has been subjected to similar environmental conditions for a sufficient period of time to impress by natural selection and survival of the fittest a change in disposition. The Jews afford the best instance of a pure race whose history is known since they were an agricultural, pastoral, and warlike people. The remarkable description of the Jew by Nietzsche in *The Dawn of Day*, which I will quote, affords an explanation.

"One of the spectacles which the next century will invite us to witness is the decision regarding the fate of the European Jews. It is quite obvious now they have cast their die and crossed their Rubicon; the only thing that remains for them is either to become masters of Europe or to lose Europe as they once centuries ago lost Egypt, where they were confronted by similar alternatives. In Europe, however, they have gone through a schooling of eighteen centuries such as no other nation has ever undergone, and the experiences of this dreadful probation have benefited not only the Jewish community, but even to a greater extent the individual. As a consequence of this the resourcefulness of the modern Jews both in mind and soul is extraordinary. Amongst all the inhabitants of Europe it is the Jews least of all who try to escape from any deep distress by recourse to drink or to suicide, as other less gifted people are prone to do. Every Jew can find in the history of his own family a long record of instances of the greatest coolness and perseverance amid difficulties and dreadful situations, an artful cunning in fighting with misfortune and hazard. And above all, it is their bravery under the cloak of wretched submission, their heroic *sperrere se sperni* that surpasses the virtues of all the saints. People wished to make them contemptible by treating them contemptibly for nearly twenty centuries, and refusing them access to all honourable positions and dignities, and by pushing them further down into the meaner trades, and under this process indeed they have not become any cleaner, but not contemptible. They have never ceased for a moment from believing themselves qualified for the very highest functions, nor have the virtues of their sufferings ever ceased to adorn them. Their manner of honouring their parents and their children, the rationality of their marriages and marriage customs, distinguish them amongst all Europeans. Besides this, they have been able to create for themselves a sense of power and eternal vengeance from the very trades that were left to them (or to which they were abandoned). Even in palliation of their usury we cannot help saying that without this occasional, pleasant, and useful torture inflicted on their scornors, they would have experienced difficulty in preserving their self-respect for so long. For our self-respect depends upon our ability in making reprisals in both good and evil things. Nevertheless, their revenge never urges them on too far, for they all have that liberty of mind, and even of soul, produced in men by frequent change of place, climate, and customs, of neighbours or oppressors; they possess by far the greatest experience in all human intercourse, and even in their passions they exercise the caution which this experience has developed in them. They are so certain of their intellectual versatility and shrewdness that they never, even when reduced to the direst straits, have to earn their bread by manual labour as common workmen, porters, or farm hands. In their manners we can still see they have never been inspired by chivalrous and noble feelings, or that their bodies have ever been girt with fine weapons; a certain obtrusiveness alternates with a submissiveness which is often tender and almost always painful. . . . Europe may some day fall into their hands like a ripe fruit, if they do not clutch at it too eagerly."

It appears as if Nietzsche's prophecy is likely soon to come true.

We cannot think that even twenty centuries have changed the bodily condition of the Jew or even his mentality in its fundamental characters, but the highest psychic level of the brain which has been latest developed evolutionally (being the most plastic) is the most capable therefore of being modified in its modes of adjustment to environment. Only those Jews who were possessed of the highest mental faculties and capacity of making new adjustments in the struggle for existence during this long period of adversity have survived. It may be assumed that quickness of apperception

and readiness to seize opportunities have developed a high degree of racial plasticity of the cerebral cortex in connexion with its evolutionally latest functions associated with the social instinct—an instinct which by natural selection and survival of the fittest in the course of eighteen centuries of persecution has taken on certain specific racial characters described by Nietzsche. But this high degree of plasticity is necessarily associated with a greater liability to mental instability, and I believe this more than intermarriage is responsible for the high percentage of psycho-neuroses and psychoses in Jewish stocks, often, however, associated with genius or great talents in the arts and sciences.

#### 4. Dispositions Impressed by Familial Ancestry.

"Like tends to beget like."

All the broad facts concerning dispositions impressed by familial ancestry were known to the ancients, as is clearly shown by the poet and philosopher Lucretius, who in *De Rerum Natura* says:

"Sometimes, too, the children may spring up like the grandfathers, and often resemble the forms of their grandfathers' fathers, because the parents often keep concealed in their bodies many first beginnings mixed in many ways, which first proceeding from the original stock, one father hands down to the next father, and then proceeding from these, Venus produces forms after a manifold chance, and repeats not only the features but the voice and hair of the forefathers; and the female sex equally springs from the father's, and males go forth equally from the mother's body, since these distinctions no more proceed from the fixed seed of one or other parent than our face and bodies and limbs. Again, we perceive that the mind is begotten along with the body and grows old along with it."

It was the custom, you remember, of noble Romans to carry in their triumphant processions the masks of their ancestors, consequently many of these facts became apparent to them.

A study of numbers of pedigrees has clearly demonstrated the fact that it is necessary in the study of hereditary mental dispositions to ascertain the presence or absence of a neuropathic tendency in all the members of the parental stocks. A neuropathic tendency may show itself in many ways—for example, eccentricity, genius, insanity, hysteria, epilepsy, neurasthenia. These mental dispositions may, like bodily conditions, be transmitted. It follows, therefore, that fundamental mental dispositions are likewise inherited.

#### The Raw Material of Character.

The raw material of character is a complex of dispositions impressed upon the individual by sex, species, race, and ancestry, giving each individual a specific predetermined plasticity to receive and store certain impressions and react to them in a particular way. This raw material of inheritance, upon which psycho-physical energy, durability, educability, imagination, temper (for example, sanguine, phlegmatic, irascible, timorous, melancholic), emotivity, moral sense and aesthetic sense, upon which personality so largely depends, is inborn. That these fundamental dispositions of mind are begotten with the body, and predetermine in great measure character and conduct, was clearly proved by the results of Francis Galton's inquiry into the history of similar and dissimilar twins, which showed that dissimilar twins remained dissimilar in mental and bodily characters although brought up together under the same conditions, while similar twins brought up in different environment remained similar in mental and bodily characters.

A good raw material inheritance requisite for survival in the struggle for existence postulates an adequate combination of mental energy and mental sagacity. Nurture can exercise a marked influence on the development of mental energy by ensuring bodily health and strength during development, and by education and upbringing in a healthy mental environment it can develop, without wasting mental energy, the inborn potentialities essential for efficiency in the struggle for existence. Nurture, however favourable, cannot give mental sagacity if it is not inborn, nor can it do more than bring out the good qualities that the raw material of inheritance has provided; but it must be remembered that nurture plays an all-important part in the preservation or the spoiling of good raw material in all classes and grades of society. However paradoxical it may seem, nevertheless it is true that the inborn virtue of an unselfish, confiding, amiable, and optimistic nature may be the cause of an acquired vicious character under the influence of evil suggestion and imitation; whereas a calcu-

lating, suspicious, and selfish nature under similar circumstances would escape contamination.

"Virtue itself turns vice, being misapplied,  
And vice sometime 's by action dignified."

Romeo and Juliet.

#### Inborn Qualities in Relation to Mental and Nervous Diseases.

If inborn good qualities are deficient or absent there will be, in spite of favourable environment after birth, intellectual, aesthetic, or moral feeble-mindedness of various forms and gradations, which in extreme cases can be shown by defective brain, the organ of mind. If there be inherited a disproportion and lack of harmony and integration of these inborn factors of the raw material in a family or stock, upon which mentality is based, an unbalanced mind is likely to develop in one or more members of the family or stock, which will show itself in various departures in conduct from that of the normal stable individual; it may be in the form of eccentricity, of fanaticism, of mysticism, of insanity, of genius, for, as Dryden said,

"Great wits are sure to madness near allied,  
And thin partitions do their bounds divide."

Again, the unbalanced mind may show itself in the form of such neuroses as hysteria, neurasthenia, epilepsy, or in one of the forms of the true insanities. The etiology of the psycho-neuroses and psychoses and their clinical symptomatology point to the fact that they belong to one great group.

#### The Neuropathic Inheritance.

There are individuals born of sound stocks that no acquired conditions—for example, drink, poisons engendered within the body or taken from without, head injuries, emotional shock, distress, and even profound misery and destitution combined—can render insane. A striking fact of this was shown in a report of Bonhoeffer, who had charge of 10,000 Serbian prisoners who had been subjected to every form of stress from disease, famine, and hardships of every kind, yet there were only five insane among them. There are others, generally from a neuropathic stock, whose mental equilibrium may be disturbed by any one of these conditions of stress, or, very frequently, without any apparent cause except the conditions appertaining to the sexual functions and reproduction in adolescence, and the puerperium and the climacteric period in women.

A careful inquiry into the family histories of the progenitors and the collateral members of ancestral stocks will in the great majority of cases show that a child born sound in mind and body is begotten by parents sound in mind and body themselves, whose stocks are free from any neuropathic or physical taint. Such a child with a good inheritance is very unlikely to suffer in later life with feeble-mindedness, epilepsy, insanity, or functional nervous disease. Occasionally, however, from some inexplicable cause parents of sound stocks may beget an idiot or imbecile child, or a child who in later life becomes insane or epileptic. In some of these cases there is a history of insanity or neurosis in grandparents or in collaterals.

The child may give evidence of mental defect by being dull and backward in learning, or it may exhibit fits of uncontrollable temper without cause, or other signs of nervous irritability, such as convulsive attacks, which may be precursors of true epilepsy or of dementia praecox. If the child escapes any distinct morbid manifestation during childhood there is a danger of its showing vicious tendencies later, or developing insanity or epilepsy at the period of adolescence when the sexual instinct is aroused and new desires and passions stimulate the brain to a new activity.

#### Natural Selection and Survival of the Fittest.

Dr. John Macpherson<sup>3</sup> has shown that the psycho-neuroses and psychoses are found in primitive people, in savages, and in all civilized nations in different parts of the world. The symptoms have a local coloration according to the beliefs, customs, usages, and traditions of the people, but they are essentially similar and doubtless have a similar causation. We may not know what this bodily causal condition is, but the clinical signs and symptoms point to its being some process causing disorder of the latest developed structure of the brain—the cerebral cortex. In cases where the psychosis terminates in a progressive dementia an organic disease of this structure is found, which would account for the symptoms.

In the primary dementia of adolescence there is a degeneration of the cortical neurones which would account for the disintegration of the psychic unity, and I have shown that associated with this is a regressive atrophy of the reproductive organs. These are obvious bodily changes, but it is probable that there is throughout the body a defective vitality—*élan vital*. There is certainly a lowered resistance to disease, as shown by the evidence of deficient oxidation processes.

I have found, by a study of the age of onset of insanity of parents and offspring in over 4,000 relatives who are at present or have been in the London asylums, a signal tendency of the offspring of insane parents to develop signs of insanity in adolescence. The average age of the parents is about 17 years more than that of the offspring. This accords with Darwin's law of Antedating or Anticipation. Those individuals who suffered with dementia in adolescence would have little chance of surviving the struggle for existence among primitive people and savages. Among civilized people insanity leads to segregation, and thus prevents propagation. The regressive atrophy of the testes in males would also interfere with propagation. Again, females predisposed by hereditary tendency break down in adolescence under the stress of normal physiological conditions, such as pregnancy, parturition, or lactation. These cases of so-called puerperal mania often terminate in dementia, and we find in them a regressive atrophy of the ovaries. Only about 10 per cent. of the primary dementia female cases in asylums are married women, and very few of these have had more than one or two children. If it were not for this natural process of preservation from breeding of such unsound members of a stock by bringing the disease on at an earlier age and in an incurable form, racial degeneracy and extinction would be inevitable in a civilization where altruistic sentiment has interfered with the struggle for existence and survival of the mentally and physically fittest.

#### *The Effect on the Individual of the Social Instinct.*

The three primal instincts, common to men and animals, of self-preservation, propagation, and the instinct of the herd, are the springs from which the streams and rivers of mental activity have their source. The bond of union of the herd is based upon the willingness of each member to sacrifice self-interest, and even life, for the common good, and by thus doing directly ensuring the preservation of the species, and indirectly the individual. The herd instinct has played a most important part in peace and war; in fact, the history of nations has depended upon it. This gregarious instinct has been the great stabilizing force in the fixation of traditions, customs, and social usages of successive civilizations in the world's history. Patriotism, moral, and discipline have their roots in this instinct, yet every successive age has shown that progress in religions, ethics, the arts and sciences, has originated in men and women with a belief in their individual mentality—so strong, indeed, that they were willing to court death, torture, or exile in their endeavour to overthrow traditional dogma and superstitions, or to incur disapprobation by not conforming to the traditions, customs, and social usages of the herd. Patriots, preachers, prophets, philosophers, artists, and scientists have in all ages and in all civilizations, at one time or another, been regarded by the herd either as bad men or mad men when, inspired by imagination and courage of conviction, they have refused to admit the truth of the accepted doctrines of the society in which they lived. What an inestimable benefit such men have conferred upon mankind, for have they not made the world's history and averted a petrified civilization? A just balance between the influence of the independent original and imaginative mind of the few, and the stabilizing influence of the collective mind of the many, is the secret of social progress and the building up of a sane social heritage. Mental hygiene should, then, be largely concerned in ensuring this just balance by encouraging all those factors and conditions in education which support moral, discipline, self-sacrifice, and esprit de corps, in the home by respect and pride of family, and in schools, universities, in the services, and in industries by respect and pride of such institutions. But it must be effected without repressing or destroying that individual self-control and independent originality in thought and purposive action which is essential for national progress. All games of skill in which the individual plays not for himself, but the side, such as cricket and football, foster the right spirit, and tend to an establishment of a code of honour in which the amour-propre is centred not in the individual, but in the school or university. It must be remembered that

man by this herd instinct is eminently imitative, and therefore suggestible to good or bad influences. We can therefore understand the important part esprit de corps plays in the regiment, the ship, or the factory. The great value of esprit de corps, discipline, and moral was strikingly shown in the retreat from Mons of the Expeditionary Force. Again it was shown by the fact that the proportion of cases of shell shock and war neurosis in great measure directly depended upon the moral, discipline, and esprit de corps of the regiment, because these stabilizing forces of the group mind were always operating against individual fear and collective imitation by suggestion.

#### PSYCHOTHERAPY IN MEDICAL PRACTICE.

Medical practitioners are now realizing that the successful treatment of a vast number of patients suffering with mental and bodily disease depends largely upon the practical study of individual and social psychology. The war has borne home to us how important it is to know the nature, inborn disposition, upbringing, education, conduct, and nurture of the individual. No one has a better opportunity of acquiring that knowledge and utilizing it than the family practitioner, who by his sympathy and sound judgement has become the friend and adviser of the family. To him the patient can come, not only for the relief of his bodily pains and disease, but for relief of his mental troubles and anxieties, which are so frequently the source of the bodily disorder. I always make it a point of asking, Have you any financial difficulties? Have you any domestic difficulties? Have you anything troubling your mind which prevents natural sleep? Do you have dreams? Are they of a terrifying nature or directly or indirectly related to the sex instinct? It is a matter of experience and tact to obtain the information required, especially in matters relating to a mental conflict with a sexual basis. Great care must be taken not to put into the mind ideas of sexual perversion, although great benefit to an afflicted conscience can be effected by explaining the physiological processes of sex, and calming apprehension relating to masturbation and impotence. A practitioner who has inspired confidence will often do more to cure some of his cases of functional neuroses with attendant bodily ailments by helping to remove anxiety and its attendant depression than by medicines. Moreover, he may be consulted by parents in the upbringing and education of children, not only from the physical but the mental side.

There is an ever-growing disharmony between the physiological conditions of the sex instinct and sociological conditions. The non-gratification of this instinctive desire may be the source of a mental conflict accompanied by fear and anxiety in a large number of men and women, especially the latter. It must be a constant experience of the members of this Association to find in the history and behaviour a sexual basis for the mental trouble of their patients who are suffering from either a psycho-neurosis (for example, hysteria, hypochondriasis, or neurasthenia) or a psychosis (for example, religious mania, manic-depressive insanity, involutional melancholia, or primary dementia).

While fully admitting the fact that the study of dreams and psycho-analysis by word association, or by free association, can lead to the discovery and uprooting of a repressed mental complex of a painful nature, or of a nature which would by society be considered wicked, yet I am of opinion that there are but few doctors who possess, or who can possess, all the necessary qualifications of experience, knowledge of technique, high moral principles, tact, and delicacy of feeling to carry out successfully the psycho-analytical methods of Freud and Jung. Human beings, especially women, are suggestible, and the class of people who seek relief on account of psycho-neuroses are eminently suggestible; consequently, unless the greatest care is taken, instead of the treatment being remedial, new and worse conflicts may be installed in the mind. It has always seemed to me that the literature relating to the truths in the new psychology of the unconscious has been deprived of much of its general practical utility by enshrouding it with mythological, mystical, atavistic speculations, and pornographic and coprologic details. Such literature has been not only eagerly seized upon by pseudo-scientists who practise psycho-analysis after their own fashion, but also seized upon and read by a section of the general public impelled by curiosity regarding sexual matters. The danger thereby arises of perverted sex ideas being implanted in the minds of such people, causing them to become in some instances antisocial in behaviour.

Introversion of the mind accompanied by contemplative

fear causes loss of voluntary attention to the world around and its diversion to the personality of the individual. The result of this is a disorder of the involuntary automatic functions of the body—a disordered coenaesthesia. Such organs as the heart, the lungs, the stomach, and the intestines, which under normal conditions function automatically with phasic or periodic regularity and without the intervention of attention, now, owing to the effects of introspection and contemplative fear, are disordered in function, and consequently obtrude themselves in consciousness. This causes hypochondriasis and various forms of neurosis.

A local colour of deranged organs gives rise to various types of neurasthenia, and obsessional psychasthenia with phobias. But besides these bodily disorders of the vital functions contemplative fear and anxiety upset the delicate poise of the internal secretions of the reproductive and endocrine glands, the functions of which we are only vaguely conscious of by the bodily effects produced.

An intelligent understanding of the influence of mind on body and body on mind—mental hygiene—and its practical application by the doctor, would avoid recourse of the public to faith healing, Christian Science, the Coué cult, and other forms of treatment by suggestion, which now receive so much popular attention and acclamation.

## THE OUTLOOK OF NEPHRITIS IN CHILDREN.\*

BY

HUGH T. ASHBY, B.A., M.D.CAMM., M.R.C.P.LOND.,  
PHYSICIAN TO THE MANCHESTER CHILDREN'S HOSPITAL, ETC.

As a general rule cases of nephritis in children do better than in adults; one reason, no doubt, being that the cardiovascular system is in good order, and any rise of blood pressure which may take place has less effect.

The examination of urine in infants is often neglected because of the difficulty in obtaining a specimen. The best way to do this is to put the infant on a mackintosh so arranged that the urine runs into a small pool at the end of the bed. Another way is to hold the infant out after a long sleep.

A simple method of estimating how much urine a child (over 4 years of age) should pass in the twenty-four hours is as follows. The age of the child in years multiplied by two and a half gives the amount in ounces. Thus a child of 6 years will pass about 15 oz. ( $6 \times 2\frac{1}{2} = 15$ ); a child of 12 will pass 30 oz. ( $12 \times 2\frac{1}{2} = 30$ ).

Acute inflammation of the kidneys occurs more often as a secondary than as a primary disease in childhood. Scarlet fever is by far the commonest cause, the nephritis coming on at any time from about the fourteenth to the twenty-sixth day of the disease; it is often impossible to determine the exact date of the commencement of the nephritis, and many cases are the result of mild attacks of scarlet fever not recognized at the time. The severity of the attack of scarlet fever plays no part in the occurrence of nephritis, which may come on after severe and mild attacks alike; often, indeed, the most fatal are those which come on after an attack only recognized by the peeling. It is likely that the patient has not been looked after during the convalescence and has been exposed to cold, etc. In any child under 10 years of age who develops nephritis, scarlet fever should be borne in mind and desquamation looked for very carefully.

The occurrence of nephritis after scarlet fever varies in different epidemics, but it may be roughly estimated at about 10 per cent. The outlook is usually good, and it is rare for the nephritis to become chronic. The amount of albumin in the urine does not seem to alter the outlook, for a case with a large amount may get quite well while one with only a small amount may do badly. The worst cases are those which have remained untreated for some days and in those where there is suppression of urine, as uraemia is liable to occur. The preventive treatment consists in the greatest care being taken during the two and three weeks after the acute onset of scarlet fever, especially as regards catching cold.

Acute nephritis does, however, occur as a primary disease, or at any rate as far as we know. Thus a schoolboy, who had apparently been in good health, was noticed by his parents to be puffy in the face one morning, and on examination a large quantity of albumin was found in the urine.

Unlike the post-scarlatinal nephritis, the outlook is mostly bad in these insidious cases. They run a course of perhaps three months to two years, but complete restoration to health does not often occur. The child may get fairly well, but he is liable to further attacks, which damage the kidneys still more, till he grows waterlogged and dies. Towards the end very little urine is passed, and dyspnoea becomes a very marked feature, so that the patient has to be propped up in bed. Uraemic convulsions are also common.

It is, however, often difficult to give a prognosis, which is what the relatives want to know. The prognosis depends on (1) the general condition of the patient; (2) whether the nephritis is post-scarlatinal or idiopathic; (3) the results of the renal function tests, etc., the chief being for the ordinary man the urea concentration test.

Recently the renal efficiency test has been elaborated by Maclean and de Wesselow, of St. Thomas's Hospital. It is simple, needs no clinical laboratory, and from my own experience gives reliable information as to the state and efficiency of the kidneys. Until lately the condition of the kidneys of patients suffering from nephritis was judged solely by the amount of albumin and by the presence of casts. Now, a large amount of albumin does not necessarily mean that the outlook is bad; nor is the converse true, for a patient with a small amount of albumin may do badly.

This is where the urea concentration test or renal efficiency test is useful. It depends upon the fact that when a large dose of urea is administered to a patient with defective kidneys he is incapable of excreting urine with a high urea concentration. The Ministry of Pensions has used this test to assist in assessing patients for pensions. The details of the test are as follows:

## Renal Efficiency Test.

Starting at a convenient time, say 8 a.m., the child empties his bladder and immediately afterwards takes 10 grams of urea (15 grams for an adult) dissolved in about 3 oz. of water, flavoured with tincture of orange. The urea solution is not unpleasant to take, and there is seldom any difficulty.

At 9 a.m., or an hour later, he passes urine.

At 10 a.m., or two hours later, he passes urine again, and this specimen is kept for the estimation of urea.

The test is easily carried out, the urea being estimated by the hypobromite method and an apparatus which gives the volume of gas evolved. The apparatus can be bought complete, or it can be arranged by oneself. The percentage of urea equivalent to the amount of gas evolved may be ascertained from a table.

If the percentage of urea after the test exceeds 2 the kidneys are fairly efficient, but if below 2 their condition is unsatisfactory. The test can be carried out each week during an illness, and we can see how the kidneys improve or otherwise. The general reliability of the test and its ease of application (it takes about three minutes) should make it of great assistance in clinical medicine, and also in certain surgical conditions, such as prostate and kidney cases.

Again, if it is suggested that a patient with chronic nephritis should undergo an operation, we can, after performing the test, say whether the nephritis precludes it. There is also the test where the blood urea is estimated, but the test is beyond the scope of anyone who is not a trained pathologist.

Little need be said of the general treatment of nephritis until we come to the question of diet. It is clear that in the past we have restricted the diet too much, especially in the amount of protein allowed. Everyone needs a certain amount of protein to keep in good health. If very little or no protein is given in the food the body itself will supply waste products, so that we cannot eliminate altogether the work of the kidneys. There is no retention of nitrogenous products in a case passing albumin in the urine, and therefore there is no need to restrict the diet. Again, there is a large loss of protein each day, and all the more reason for giving a liberal supply in the food to make good this loss. When protein is given in the diet the amount of albumin in the urine is not increased and often diminishes.

A high protein diet is the best means we have of relieving a patient who has much dropsy from nephritis, and helps to make him more comfortable. This is most probably to be explained on the ground that the protein diet raises the urea percentage in the blood and so causes a diuresis, for urea is

\* A paper read to the Lancashire and Cheshire Branch of the British Medical Association, January, 1923.

one of the best diuretics we have. A dose of urea, 10 to 15 grams each morning, will often get rid of obstinate oedema. It should be noted that there is no excess of urea in the blood during uraemia; if there were there would be a good diuresis and no uraemic convulsions.

To sum up, I would advise that a patient with nephritis should have a slop diet for about ten days, and that the diet should gradually be increased to include fish, eggs, and meat, although there is still albuminuria. Also do not keep a nephritic patient in bed too long. A certain amount of exercise in a warm room helps to lessen the oedema, besides giving the child a happier time.

## IONIC MEDICATION.

BY

DAVID CAMPBELL, M.C., M.A., B.Sc., M.B.,

FOLLOK LECTURER IN MATERIA MEDICA AND PHARMACOLOGY, UNIVERSITY OF GLASGOW; PHYSICIAN TO OUT-PATIENTS, WESTERN INFIRMARY, GLASGOW.

That particular branch of therapeutics known as ionic medication or ionization is one about which very little information can be obtained in any recognized textbook of pharmacology and therapeutics. Yet the subject is not a new one. Lewis Jones states that Leduc, in one of his publications, gives references to a great many papers on the subject, and mentions one published in 1833.<sup>1</sup> Turrell goes even farther back and declares that the theory of ionic medication was enunciated by Verratti in 1747.<sup>2</sup> The general application of this theory as a practical question in therapeutics appears, however, to date from the publication of a series of papers by Leduc in 1900. In spite of this most textbooks ignore the subject. A few mention that there is such a method of treatment, but offer little or no criticism of its efficacy.

The reason for this reticence on the part of authors is fairly obvious. The majority of those who practise this method of treatment acclaim with enthusiasm the wonderful results which follow. Those who criticize it exhibit an almost equal degree of vehemence in their condemnation. It is difficult for the therapist, who may have little or no practical experience of the method, to know where the truth lies. It seemed to me, therefore, that it might serve a useful purpose to undertake a critical examination of the whole subject, basing my views on a considerable number of experiments and clinical observations.

The first difficulty which arises is in the definition of the term "ionic medication." According to those who speak with authority on the subject the term embraces (1) the introduction of drugs into the body through the skin or a mucous surface by means of an electric current, and (2) the modification of the chemical composition of parts of the body by the setting up of chemical changes throughout the tissues.<sup>3</sup> If the second part of the definition means that the chemical composition of the tissues is modified by the drugs introduced, then it is understandable. If, however, as is generally held, it means that this modification is the result of the passage of a current through the body, without any reference to the drug introduced, it is very difficult to see how this process can be termed "medication." It is obvious, in any case, that the two parts of the definition involve quite different conceptions, and will require to be considered separately.

The first question therefore which has to be considered is: Can drugs be introduced through the skin by means of an electric current? The answer to that question is undoubtedly in the affirmative. In animals Leduc showed that it was possible to introduce strychnine ions through the skin of a rabbit in this way.<sup>4</sup> Finzi proved that the ferri-cyanide ion could be carried through the skin of a monkey.<sup>5</sup> Inchley repeated these experiments on cats, rabbits, and guinea-pigs, and showed further that it was possible to introduce a number of other alkaloids, some metals, and certain negative ions.<sup>6</sup> In man exact records of experiments are few, though numerous writers have mentioned that it is possible to prove the penetration of the iodine ion. In my experiments I have been able to confirm this, and I have further been able to demonstrate quite conclusively the presence in the body of another anion, the salicylic ion, and of two cations, pilocarpine and atropine, after they have been carried through the human skin by a current of electricity.

The next question is: Has the ion thus introduced into the body any special pharmacological action in virtue of its being

so introduced? If we are to believe the ionic theory of the action of drugs—namely, that soluble salts exist in the body mainly as ions, and that each ion possesses an independent pharmacological action—then we must believe that the method of administration will make no difference to its intrinsic action. That this is so has been shown by the experiments of Leduc and Inchley on animals. The strychnine ion introduced electrically exhibited its ordinary action on the spinal cord and caused convulsions, while the atropine ion exhibited its ordinary action by producing paralysis of the cranial autonomic nerves. In man it can be shown quite easily by using a solution of pilocarpine nitrate underneath the positive pole. After the current has passed for some time the individual exhibits salivation, sweating, and disturbance of vision—in other words, the ordinary signs of the action of the pilocarpine ion. It may seem that I elaborate this point rather unnecessarily, but the suggestion has frequently been made, or at any rate implied, that by introducing an ion through the skin by means of an electric current you thereby endow it with some peculiar properties. That this is not so is obvious. The essential pharmacological action of any particular ion is the same whether it be passed through the skin into the body by innunction, a hypodermic needle, or an electric current.

If that be so the critic will very naturally ask: Wherein lies the particular merit of this method of introducing drugs into the body? The technique is expensive, complicated, and wasteful of valuable drugs, compared at any rate with the hypodermic needle or innunction. What advantages does it possess to compensate for these very obvious drawbacks? The answer is given that "in treatment by ionization a cloud of ions is introduced into the place where the disease exists"; that the ions are limited to the diseased region, and that therefore the local concentration is high. As a result the action is more intense, and the effect consequently greater.

If we examine these statements we must inquire: (a) What quantity of drug can be passed through the human skin by means of the currents used for therapeutic purposes? (b) What evidence is there of a local concentration of the drug? (c) How deeply can the drug be made to penetrate in this way?

I have investigated the first question with special reference to the iodine and salicylic ions, which are the two remedies most extensively employed in the treatment of medical conditions in this way. The method adopted was to "ionize" a number of patients, using a 2 per cent. solution of potassium iodide or sodium salicylate under the negative electrode. The process was continued for a period of thirty to forty minutes, and the urine was collected for analysis during the twenty-four hours following the experiment. The method described by Kendall<sup>8</sup> was employed to estimate the amount of iodine present in the urine, and the amount of salicyl bodies was estimated by Hanzlik's method.<sup>9</sup> The following table gives the results when potassium iodide was used.

Current in milliamperes ... ..	25	50	100	200
Milligrams of iodine in 24 hours' urine	30	55	56	145

It must be pointed out, of course, that it is not possible to raise the current all at once to the amperage indicated. For the comfort of the patient that has to be done gradually, and accordingly the currents mentioned were not acting during the whole period of the experiment. The rapidity with which the current could be raised varied with different individuals, but the quantities of iodine noted in the table were the maximum found for each particular current. In the case of the current of 200 ma. the duration of the experiment was forty minutes, the current being raised from 100 to 200 ma. during the last thirty minutes of the period. The duration in the other cases was thirty minutes.

It is known that from 60 to 80 per cent. of the amount of iodide taken into the body by any channel is excreted in the urine in twenty-four hours. From the figures given it is possible therefore to estimate approximately the amount of the iodine ion which has entered the body. Taking even the lowest percentage, the maximum amount of iodine which was introduced into the body by each current was 50, 92, 160, and 245 mg. respectively. In other words, it will be seen that, with the ordinary currents used in therapeutics, and for the ordinary duration of treatment, the total amount of iodine introduced was not greater than 0.77 grain, 1.4 grains, and

2.46 grains. Even with the huge current of 200 ma. the amount was only 3.74 grains.

When sodium salicylate was used the amount of salicyl bodies excreted in the urine, after the employment of ordinary currents, was so small that it could not be estimated with any degree of accuracy. Using a current rising to 170 ma. during a thirty-minute period, the total amount of salicyl bodies found in the urine was only 9 mg. It is interesting to note that this result coincides with that of Inchley, using a cat as the subject of experiment.<sup>6</sup> He found only very small amounts of salicyl bodies in the urine, and comments on the fact that the salicylic ion is not carried through the skin to the extent that enthusiastic writers on the subject would lead one to suppose.

Objection may be taken to this process of reasoning. It may be argued that the amount excreted would give no true indication of the amount passed through the skin. The objection has very little weight, but it can easily be overcome by considering the results when pilocarpine nitrate and atropine sulphate were used. With pilocarpine nitrate, using a current rising to 50 ma. over a period of twenty minutes, there was produced in the subject of the experiment salivation, sweating, and slight disturbance of vision. All these effects could be produced on the subject and to the same degree by injecting 1/5 grain hypodermically. In the case of atropine sulphate it was not considered advisable to use large currents because of the poisonous effects of very small quantities of that drug. But using a current of 5 ma. for thirty minutes resulted in sufficient atropine being introduced to produce a rapid pulse (135 a minute), marked dryness of the mouth and throat, and paralysis of accommodation lasting for eighteen hours. All these symptoms could be produced by injecting hypodermically 1/30 grain of atropine sulphate. In these experiments the amount of the drug introduced into the body was estimated, not from the amount excreted, but by its physiological action, and in each case it will be seen that this amount was small. It will be noted, further, that the action of these drugs differed in no way from what is seen when they are given hypodermically.

While the salient feature of all these results is that the amount of drug introduced is very small, there was another feature which is of considerable importance and which bears on the question of local concentration. In "ionizing" a patient with potassium iodide it was possible to demonstrate iodine in the saliva collected during the first twenty minutes of the period of treatment. Again, when pilocarpine nitrate was used, salivation made its appearance twelve minutes after the current was started; exactly the same time as after hypodermic injection. Where, then, is the evidence of local concentration? It must be quite obvious that as soon as the ion is carried through the skin it is whisked off in the blood stream and that therefore no local concentration ever takes place. Otherwise how is it possible to explain its appearance so quickly in parts of the body so far removed from the seat of entry, and in such amounts as to produce its physiological action on these parts?

The next question to consider is the depth of penetration of the ions. In man it is difficult to produce any experimental evidence to bear on this question, but the discussion in the previous paragraph throws some light upon it. If the ions introduced through the skin appear so rapidly in distant parts of the body, it must be obvious that they are set free from their function of carrying the electric current as soon as they pass through the skin. That they penetrate deeply is therefore unlikely. It should be noted further that although, until it passes the barrier of the skin, the current can be conveyed only by the ions of the solution underneath the electrodes, as soon as this barrier is passed the ions of the body fluids will take on the task of carrying the current. That fact renders even more unlikely deep penetration of the foreign ions introduced. A number of experiments have been related to prove that ions penetrate deeply. These experiments are, however, useless for this purpose. They only show that it is possible for considerable penetration to take place in dead or isolated tissue and in parchment. In the living body there is quite a different state of affairs.

In the few cases where attempts have been made to show deep penetration of ions in man they have signally failed. Finzi, in monkeys, claimed that he had been able to obtain penetration of the ferri-cyanide ion into the knee-joint.<sup>6</sup> Grave doubt has to be cast on this experiment because of the possibility of the ferri-cyanide ion found in the joint being carried there by diffusion after the animal was killed. Finally, Inchley, repeating this experiment on a rabbit, found

that there was no deeper penetration into the joint than could be obtained by simple subcutaneous injection of the drug under the skin covering the joint.<sup>6</sup> The whole weight of experimental evidence in living animals goes to show that the penetration of ions is not deeper than the subcutaneous tissue.

It would appear, therefore, that the following statements are true:

1. The amount of any drug introduced in an ionic state into the body by currents which can be used therapeutically is very small.
2. The drug, as soon as it is carried through the skin, is swept away in the blood stream and produces its specific action on the system generally. There is therefore no local concentration.
3. There is no evidence of deep penetration. On the contrary, in animals the experimental evidence is all against the drug penetrating farther than the subcutaneous tissue. In man it seems to be quite clear that a similar state of affairs exists.

We have now to examine the second part of the definition—namely, that in the process of ionization chemical changes are set up in the tissues, and that the resulting modification of the chemical composition of the body produces a therapeutical effect. That statement, as will be obvious, has really nothing to do with medication, but is a claim for the action of a constant current of electricity. An example of this is the claim that there is a "lytic" action underneath the negative electrode, and that this "lytic" action affects principally exudates and recently formed bands of lowly organized tissue.<sup>10</sup> It is quite true that, when an electric current is passing through the body fluids, there will be movement of anions towards the positive pole and of cations towards the negative pole. But it does not follow that any chemical changes are set up in the tissues between the poles. Faraday demonstrated long ago that when a current is passed through a solution of an electrolyte no apparent change occurs in the fluid, and that chemical changes take place only at the electrodes. To take a concrete example: when a current is passing through a solution of sodium chloride no chemical change can be observed in the solution, although the ions are in motion to their respective poles. At the negative electrode the sodium ion will give up its electrical charge, become a sodium atom, and combine with water to form a caustic alkali which will act on any tissue in contact with it. But that is at the electrode and, in the cases considered, on the skin. To suggest that any ion of the body fluids can produce a "lytic" action on the tissues underneath the skin before it has reached an electrode is manifestly absurd. There can be no "lytic" action except on the skin underneath the negative electrode. Further, it is difficult to conceive, and there is no evidence to suggest, that the mere migration of an ion, which is normally a constituent of the body fluid, to another part of the fluid can cause any chemical change which would have a therapeutical effect.

Certain authorities, recognizing the difficulty of explaining their therapeutical results on the basis of chemical changes in the tissues, have claimed that it is the movement of the ions which is the important factor. They suggest that there is a bombardment of millions of tissue ions on the affected part and that this "ionic massage" may be of benefit. In the present state of our knowledge of the forces bound up in matter it is hardly worth while discussing such a hypothesis. Two facts, however, are worth mentioning: (1) Though the number of ions set in motion must be enormous, the total mass of ions acting on any part must be very small; (2) the greatest migration velocity of any ion, the hydrogen ion, with a potential gradient of one volt per centimetre is only 0.0032 cm. a second.<sup>11</sup> It is difficult to see how a "bombardment" carried on by a small mass moving so slowly can have much effect. It can be in no way comparable to massage at the hands of a well trained expert.

In view of these facts I have been inclined to regard closely the therapeutical value of this method of treatment in a number of cases in the Western Infirmary, Glasgow. In a number of cases in the Western Infirmary, Glasgow. Potassium iodide and sodium salicylate, each in 2 per cent. solution, were the drugs used, and the cases which were treated were patients suffering from fibrositis of the lumbar and other regions, sciatica, and rheumatoid arthritis. As a general rule currents up to 100 ma. for thirty to forty-five minutes were employed; in one case a current of 170 ma. was reached during the last ten minutes of a thirty-minute period of treatment. The results can be briefly summarized. In no case was there any real benefit. The results agree with those

obtained by Stockman in an extensive investigation of the treatment of the same conditions by ionization. These were not published in detail, but an epitome of them is to be found in his book on *Rheumatism and Arthritis*.<sup>12</sup> Nor could it be expected that it is possible to cure such diseases in this way. For iodides and salicylates can be administered by the mouth in doses sufficient to produce a continuous concentration of iodine or salicylic ions in any part of the body far greater than could possibly be produced by ionization. Further, very much greater quantities of salicylic ions can be passed locally through the skin by applying methyl salicylate, and much greater quantities of iodine ions by applying iothion (di-iodohydroxypropan), an oily liquid having the chemical formula  $\text{CH}_2\text{I} \cdot \text{CHOH} \cdot \text{CH}_2\text{I}$ . Yet none of these methods of treatment benefits the conditions mentioned.

Although no real and permanent benefit followed this method of treatment, in a number of cases there was a temporary relief of pain. This relief persisted for some hours after the process of ionization, but in every case the pain returned, though in a few cases not to the same extent. This diminution of pain could in no way be ascribed to the introduction of the iodine or salicylic ions, for an exactly similar diminution of pain was obtained when the current was reversed and therefore no iodine or salicylic ions were being introduced. Similarly, when a pad soaked in a solution of sodium chloride was used over the affected part the same relief was observed.

It would be of interest to inquire as to the particular factor to which this is due. It has been shown conclusively that it is not due to the specific action of any ion. It must be due, therefore, to the galvanic current. Two different factors will thus require to be considered: (1) the current passing between the poles, and (2) the action of the current at the poles. Turrell suggests that the action of the current passing between the poles has the effect of generating an appreciable increase of temperature in the tissues, and to this increase of temperature he ascribes the beneficial result which follows.<sup>13</sup> It is true that Joule's law applies to electrolytes, and that therefore all the energy of the current spent when traversing the electrolyte is used simply in the production of heat, and not in causing chemical changes. But the most of the heat produced in this way is on the skin where the resistance to the current is greatest, while that produced in the tissues underneath the skin is small, is slowly evolved, and is dissipated quickly throughout the body. The experiments Turrell brought forward in support of his view merely showed an increase of the surface temperature of the limb to which the electrodes were applied, and that could quite easily be caused by dilatation of the cutaneous vessels. He admitted further that the more powerful heat-producing action of the diathermy current was not nearly so good as the ordinary galvanic current. His attempt to explain this obvious difficulty is not convincing.

It has to be admitted that the passage of an electric current through the tissues will have a general stimulating effect on them which may be of some benefit. But to me it seems clear that it is the action of the current at the poles which is the chief factor in the relief of pain. In every case treated in this way there is some irritation of the skin under the pads, which is evident from the sensations of the patient and from the marked hyperæmia of the skin seen when the pads are removed. This irritation is produced partly by the electrolysis of the substances in the solution employed to moisten the pads and partly by the stimulating action of the current on the skin, and it is sometimes sufficient to cause a tender part of the skin to remain red for several days. Nor is it necessary to use very large currents to produce this irritation. For, while the amount of irritation varies directly as the current, it varies indirectly as the size of the electrode. It is possible, therefore, to get a considerable amount of irritation even with small currents, if small electrodes be used. Here, then, is the ordinary counter-irritant action. It is difficult to account for the manner in which counter-irritants produce their beneficial effect, but that they do relieve deep-seated pain, at any rate temporarily, is undeniable. It seems to me therefore that, while it is possible that the interpoler current has some general stimulating effect on the tissues underneath the skin, the great factor in producing temporary relief of pain is the counter-irritant action on the skin underneath the electrodes.

So far only the medical aspect of ionization has been discussed. As far as its surgical application is concerned, those who practise this method in the treatment of many different varieties of septic sinuses, lupus nodules, and septic diseases

of the vagina and uterus, claim that the results obtained are excellent. I have had no practical experience of its use in these conditions, and can therefore offer no opinion as to its therapeutical efficacy. But, as far as the theory is concerned, attention may be drawn to the following facts. Zinc is the ion which is used in practically all cases. A number of electrotherapeutists use simply a zinc probe, which is put into a sinus, or a zinc sound, which is passed into the uterus, the metal forming in each case the positive electrode. When a current is passed the metal will have a destructive action on any tissue with which it is in contact. The chlorine ions of the tissues will move to the zinc electrode, give up their electrical charges, and the chlorine atoms thus set free will combine with the zinc of the electrode to form nascent zinc chloride. This substance will produce its well recognized caustic action on the tissues and its antiseptic action against any organisms which are present. But that is not "ionic medication." It is simply a method of producing nascent zinc chloride electrolytically in a place where its action may be of value. That a similar state of affairs exists when the zinc rod is placed in a cavity containing a solution of zinc sulphate is most likely, for here there will be constantly produced, electrolytically, nascent zinc sulphate by the sulphuric ions giving up their electrical charges at the zinc electrodes, and the atoms thus formed combining with it. In addition, the irritation of the tissues under the electrode will cause an increased blood supply to the part, which, in the chronic conditions in which ionization is employed, will be of some benefit. That there is any deep penetration of zinc ions is very doubtful, and it is not desirable in view of the powerful coagulating effect which zinc ions have on the albumin of the tissues. It appears to be entirely unnecessary to invoke the conception of the deep penetration of zinc ions in order to explain the therapeutical results which follow ionization. The combined action of the compounds formed electrolytically at the zinc electrode and the irritation of the tissues is quite sufficient to produce all the effects which have been described.

In conclusion, it will be obvious that, if the argument presented above is accurate there is very little scientific basis for the theory of ionic medication, and—as far as, at any rate, as the medical aspect is concerned—for the practice thereof. To those who strongly support this theory I may appear guilty of an excess of zeal in attempting to undermine their hypothesis. In defence I can only draw their attention to the words of Claude Bernard: "In science the word criticism is not synonymous with the word disparagement; to criticize means to seek the truth by distinguishing what is true from what is false."

## RHEUMATOID ARTHRITIS TREATED WITH INTRAVENOUS BACILLUS COLI VACCINE.

BY

ROWLAND J. PERKINS, M.D., B.S. LOND., M.R.C.P.,  
PHYSICIAN WITH CHARGE OF OUT-PATIENTS, ROYAL WATERLOO HOSPITAL;  
AND

G. BRUCE WHITE, M.B., CH.M. SYD.,  
LATE HOUSE-PHYSICIAN, ROYAL WATERLOO HOSPITAL.

By rheumatoid arthritis we mean the type of chronic arthritis of infective origin attacking the small and large joints, and characterized by proliferative changes in the ligaments and effusion into the cavity of the joints, and going on to ankylosis. Commonly, this type of case is considered to be of chronic infective origin, the infection arising from some hidden focus in the body, common foci being the teeth, tonsils, alimentary canal, and urogenital system, the latter being particularly common in women. We wish to draw a distinction between this type of case and the type of osteo-arthritis occurring in old people and characterized by

osteophytic growths and erosion of the articular surfaces, but showing practically no tendency to ankylosis. In this type the changes are rather of a degenerative nature.

Treatment of rheumatoid arthritis may be classified under three headings—namely: (1) Elimination of the focus of infection; (2) increasing the resistance of the patient to the infection; (3) local treatment to the joint—(a) to prevent deformity; (b) to alleviate pain; (c) to preserve movement of the joint.

Frequently, however, the focus of infection is difficult to locate, and, although routine search was made in all cases under our care, in most no such focus could be found. It is in these cases, in which the preparation of the vaccine from the focus of infection was impossible owing to a definite focus being absent, that the protein shock method by the intravenous use of *B. coli* vaccine was employed. Our search for foci of infection was necessarily limited owing to our patients (all except one) being out-patients during the treatment, except when admitted for the actual injection for twenty-four to forty-eight hours.

The normal defences of the body in the average case of rheumatoid arthritis are low, as is shown by the absence of leucocytosis in most cases, even in those in which a pyogenic coccus can be demonstrated in the focus of infection. The object of the protein shock is to make a sudden call on these defences with the idea of arousing them from their apathy. The *B. coli* vaccine was used owing to its being a form of protein suspension convenient to administer, and the material for its preparation is always easily obtainable. Possibly there may also be a specific action as well in some cases, in that *B. coli* may be the infection of some of those in which no focus of infection could be discovered.

The vaccine was given intravenously in doses varying from 50 to 200 millions for a first dose, the patient being admitted for twenty-four hours, as it was considered that the reaction was too severe for the patient safely to remain an out-patient whilst it was in progress. A certain amount of difficulty was experienced in judging a suitable initial dose. This should be as large as possible, and we found that the general condition of the patient was a much better guide to the initial dose than the condition of the joints.

The reaction usually consisted of a rise of temperature occurring a few hours after the injection, the temperature varying from 100° to 103° F., and frequently accompanied by a rigor. Nausea and vomiting may also occur. The duration of the reaction varies from twelve hours to two days. If any improvement as a result of the treatment is to take place it does so rapidly, and, as a rule, within two days, though in one case (F. S.) there was very little immediate improvement, but this occurred three weeks after the injections. If the reaction is too severe it can be checked by giving min. 5 of 1 in 1,000 adrenaline chloride solution intravenously; but in none of our cases did we find this to be necessary. Those cases with the severe reaction showed the best results.

#### Case 1.

Mrs. W., aged 43. Attended July 10th, 1922, complaining of swelling and pain of finger-joints of eight years' duration. On inquiry she stated that she had slight vaginal discharge.

Examination showed swelling of wrists and finger-joints, and a good deal of tenderness and limitation of movement. Heart: Mitral regurgitation present, but good compensation. Vagina and cervix uteri: No evidence of discharge found, and no cervicitis.

One hundred million *B. coli* vaccine were given intravenously with moderate reaction. Marked improvement followed; pain disappeared, and the swelling diminished considerably; stiffness was, however, still present.

On July 27th 500 million were given with moderate reaction and good result to joints.

The patient still has slight swellings of the joints, but movement is practically normal and painless.

#### Case 2.

Doris M., aged 26. Attended June 21st, 1922, complaining of pain and swelling in finger-joints for some time, and recently pains in shoulders and knees.

Examination showed early rheumatoid changes in fingers, with limitation of movement. No swelling, but slight limitation of movement of right shoulder-joint. No oral, nasal, or other septic foci discovered.

On June 26th she was given 100 million *B. coli*. There was a severe reaction, with marked fever (103° F.) for three to four days, intermissions, pallor, asthenia, and sweating. Within twelve hours of the injection there was distinct improvement of the joint condition. The swelling and pain disappeared, and movements became free. Five weeks later there was some return of symptoms, and the patient was readmitted and given 500 million intravenously, with improvement. The patient has remained well since.

#### Case 3.

F. S., aged 59. Admitted June 6th, 1922, with extremely marked rheumatoid changes of about five years' duration in all the joints of both upper and lower limbs. There was inability to extend the elbows beyond the right angle, practically no movement in wrists, inability to extend knee-joints above 150 degrees; she was unable to walk, but could stand with difficulty. Patient had previously had treatment at various spas, including vaccine treatment, subcutaneously by vaccines from teeth. The teeth were found to be very septic, and marked pyorrhoea was present, but there were no dental abscesses.

Weight extension was applied to the knee-joints, extraction of all teeth was performed, and three doses, of 500 million, 1,000 million, and 2,000 million respectively, of *B. coli* vaccine were given intravenously at intervals of ten days. The reactions were mild, though after the second dose an additional soft swelling appeared in the metacarpo-phalangeal joint of the right index finger, and persisted a few days before disappearing. Immediate improvement in the joints was practically nil, but since her discharge considerable improvement has occurred, and when last seen (September, 1922) she could walk moderately well with the aid of two sticks, and she was then able to extend both knee-joints. The pain was less but still persisted; subsequently, however, except for slight recurrences during damp weather, this disappeared.

#### Case 4.

L. G., aged 37. Attended February 2nd, 1922, complaining of pain and stiffness in fingers and wrists. On examination there was found to be considerable swelling of all the small joints of the hands, with marked stiffness. No Heberden's nodes were present. Some pyorrhoea alveolaris was present in the mouth. Dental sepsis was healed by extraction, and a trial made of potassium iodide and guaiacol carbonate by mouth, with little or no improvement.

On March 30th the patient was given 50 million *B. coli* intravenously. The reaction was slight and consisted of two days' pyrexia. The affected joints became less swollen and freely movable. A relapse occurred about six weeks later, and 150 million were given on April 13th and 250 million on April 18th, the latter dose being given because the former failed to produce sufficient reaction. A slight reaction was produced by the second dose and the results to the joints were good. Since then the joints have remained free from pain and stiffness, but slight spindle-shaped swelling of the fingers persists.

#### Case 5.

A. R., aged 44. Attended May 4th, 1922, complaining of "rheumatism" for two months. Examination showed rheumatoid arthritis in smaller joints of the hands, oral sepsis, and septic tonsils. The teeth and tonsils were treated by extraction and antiseptic paints respectively, and the patient was given a mixture containing potassium iodide and guaiacol carbonate, but no improvement resulted. She was then given 50 million *B. coli* vaccine intravenously, and there was immediate improvement in the affected joints; the swelling subsided and the pain was relieved. Seven weeks later there was some return of the symptoms, and 200 million *B. coli* were given intravenously and improvement again resulted. Since July 6th the patient has not reported to the hospital.

#### Case 6.

E. B., aged 52. Attended on February 21st, 1922, complaining of pains in wrists and legs for two months. Examination showed swelling of small joints of hands and right knee; some oedema of ankles present. Some dental sepsis present.

The patient was under treatment for five months with local applications and medicine, and dental sepsis was treated. On June 22nd the patient was admitted and was given 100 million *B. coli* vaccine intravenously, with very good results to the joints and a moderate reaction. Since this the patient has reported fortnightly, and now states that she is practically free from pain, and that, whereas prior to treatment she was unable to dress herself, she can now do so.

#### Conclusions.

The number of cases under review is small, so that it is premature to draw any hard and fast conclusions. However, though we do not claim in any way that this treatment is a final and lasting cure for the condition, to us the treatment does appear to have definite value, especially as an adjuvant to the more recognized methods of treatment. It is also too early to state whether any benefits that may have resulted are permanent.

We consider it to be indicated under the following conditions: (1) Cases in which no definite focus of infection can be located. (2) Cases in which the more recognized methods have failed. (3) Early cases in which the process in the joints is still active, especially if swelling and effusion be present. Case 3 indicated that little can be hoped for when adhesions are present in the joints.

A great difficulty experienced with the treatment was to estimate the dose of vaccine required to produce a beneficial reaction which would not be too severe for the patient. We are of the opinion that we erred on the side of leniency in this respect and that too small doses were given.

In conclusion, we desire to express our indebtedness to Dr. Woodwork for the loan of beds for our cases during the period of reactions.

FOREIGN BODIES IN THE AIR AND FOOD  
PASSAGES.

## REMARKS ON FIVE CASES.

BY

C. A. SCOTT RIDOUT, M.S.LOND., F.R.C.S.ENG.,

SURGEON TO THE EAR, NOSE, AND THROAT DEPARTMENT OF THE  
PORTSMOUTH AND SOUTHERN COUNTIES EYE AND EAR  
HOSPITAL; ASSISTANT SURGEON TO THE ROYAL  
PORTSMOUTH HOSPITAL.

The following series of 5 cases of foreign bodies in the air and food passages form an interesting group illustrative of the value of modern treatment for these conditions, and of the necessity of having at hand the most up-to-date instruments for dealing with them; this was shown especially by the one failure to remove the foreign body by endoscopic methods, recourse to the older and cruder surgical method of external incision becoming a necessity.

## CASE I.—Toothplate Impacted in the Right Bronchus.

J. S., a mechanic aged 22, was referred to the Eye and Ear Hospital by my colleague Mr. Bosworth Wright on October 25th, 1922, with the following history. On October 24th he lay down about 6 p.m. and fell asleep; he woke about an hour later, coughing, and felt pain in the right side of the chest. He then missed his lower toothplate, which contained ten teeth and had one holding hook. Past history elicited that on a few occasions he had suffered from petit mal, becoming unconscious for a short period. The cough and pain in the chest continued, and he went to the Royal Portsmouth Hospital, where by screening with x-rays a foreign body was located to the right of the middle line of the chest opposite the fifth rib posteriorly. An oesophageal bougie passed easily. He was transferred to my care next day, and on further screening the foreign body was seen in the same place as before to the right of the middle line of the chest, whether screened from front or back. A radiograph confirmed the appearance seen in the screen. Cough was frequent and painful. Loud rhonchi were heard over the centre of the right pulmonary area. It was obvious therefore that a foreign body was present in the right bronchus, but its size (length as seen about 1½ inches) did not correspond to the description of the missing toothplate, though its contour corresponded to a smaller plate than the one described.

The patient was then anaesthetized by Dr. C. Mayhew, anaesthetist to the Eye and Ear Hospital, with a C.E. mixture, after injection of the pre-tracheal tissues with 2 per cent. novocain and adrenaline 1 in 20,000. A deliberate tracheotomy was performed, the second, third, fourth, and fifth tracheal rings being incised after division of the isthmus of the thyroid and injection of 1 per cent. cocaine into the trachea. The interior of the trachea was then mopped with 5 per cent. cocaine as far as the bifurcation, coughing being thereby prevented. The anaesthetic was now changed to oxygen and chloroform, given through a Eustachian catheter directly into the trachea.

Irwin Moore's internal illuminating bronchoscope was then introduced into the right bronchus, where the curve of the hook attached to the vulcanite body of the toothplate was seen. By the aid of Irwin Moore's forceps the plate was seized and brought to the tracheotomy wound, where, unfortunately, it slipped from the forceps grip, and, before the assistant was able to secure it, was sucked back into the trachea and again lodged in the right bronchus. It was again seen, seized, and brought upwards, but once more slipped from the forceps grip (the vulcanite surface was rendered extremely difficult to hold owing to much mucus) while still in the trachea, and this time fell back into the left bronchus, where it was ultimately secured and brought out through the tracheotomy wound. The trachea and bronchi had previously to this been mopped with 50 per cent. cocaine as the frequent manipulations had rendered their surface irritable.

The plate when removed was found to contain the hook end, a portion of which was missing, and five tooth sockets holding three teeth, two being empty, and the plate had evidently been broken exactly in the middle line. In order to be quite sure that nothing was left behind the bronchial tree was explored on both sides with the bronchoscope, a good view being obtained. The patient subsequently passed the other half of the plate with five teeth in five sockets per rectum, having evidently smashed the plate in half while in an epileptic spasm, and broken off two teeth as well—these latter were not recovered. After-progress was uneventful save for some mild bronchitis, for which due precautions were taken.

Noteworthy points about the case are:

(a) It would seem that, in similar cases where large and slippery foreign bodies are present in the bronchi, the position of the patient should be oblique with head slanting downwards in case of slipping of the forceps grip.

(b) The assistant should be ready with a pair of Spencer Wells forceps to secure a good grip on the foreign body whenever it appears in the wound.

(c) Tracheotomy would seem advisable in this class of case, as the foreign body was too large to be drawn through the bronchoscope, and had to be brought up together with the withdrawal of the tube, and would otherwise have certainly damaged the glottis.

(d) Anaesthesia as carried out in this case, by means of chloroform and oxygen administered through a large-size Eustachian catheter introduced alongside the bronchoscope, proved very satisfactory.

## CASE II.—Foreign Body in the Hypopharynx just Above the Entrance to the Oesophagus.

M. K., a schoolgirl 9 years of age, was admitted to the Portsmouth Eye and Ear Hospital on September 18th, 1922, with a history of having swallowed a drawing-pin while at school. A radiograph showed the drawing-pin lying slightly to the right of the middle line opposite the ring of the cricoid cartilage.

FIG. 1.—Case I: Toothplate, measuring 1½ inches in length, removed from right bronchus.

The patient was anaesthetized with C.E. mixture and an oesophagoscope introduced. At first the foreign body was not seen, the oesophagus being entered and found normal in appearance; but on withdrawing and examining the right lateral wall of the hypopharynx it was easily observed and removed with forceps.

The value of endoscopic methods was well illustrated in this case as any blind manipulation with coin catchers, etc., could only have been productive of injury owing to the sharp point of the drawing-pin, and the danger of pushing it downwards with a probang or other means is obvious. External incision would have necessitated a severe operation and probably a tedious convalescence.

## CASE III.—Mass of Fish Bones Impacted Across the Oesophagus Opposite the Sterno-clavicular Articulation.

Mrs. A. J. was seen by me in consultation with Dr. Lyth of Southsea in the spring of 1921, with a history of having swallowed a mass of fish bones whilst eating a meal, and that this was followed by great pain radiating over the lower neck and clavicular region on both sides, and inability to swallow.

The patient was anaesthetized and the oesophagoscope introduced, when the fish bone mass was seen lying transversely across the oesophagus opposite the site of pain—that is, the inter-clavicular region. The mass was seized with forceps and easily came away, affording complete relief.

This case, again, shows the advantages of endoscopic methods as opposed to the more barbarous probang which in olden days alone would have been available; a mass of bone thus situated could easily wound the walls of the oesophagus, and in such a position sup-puration or damage to large vessels in the vicinity might easily prove fatal.

FIG. 2.—Case II: Drawing-pin in hypopharynx.

## CASE IV.—Toothplate Impacted in the Oesophagus; Failure to Remove it owing to Lack of Necessary Appliances.

A. B., a female patient aged about 35, was admitted to the Royal Portsmouth Hospital in September, 1921, with a history of having swallowed a metal toothplate with pointed lateral extremities but no hooks. A radiograph confirmed the history, and showed the plate lying horizontally across the oesophagus just below the ring of the cricoid.

Under local anaesthesia an oesophagoscope was introduced and the upper edge of the plate easily located; the plate was seized with forceps, but could not be shifted owing to the fixity of its pointed lateral extremities in the walls of the oesophagus.

As I was not then in possession of Irwin Moore's shears for dividing such plates in the middle line and removing them in two halves, freeing their points of attachment in this way, and also not then having Paterson's recent expanding oesophagoscope, I was unable to continue endoscopic methods and had to have recourse of necessity to external oesophagotomy. This I performed through a somewhat unusual route. As I knew exactly the location of the toothplate, I incised the middle line of the neck, divided the isthmus of the thyroid, and retracted the left lobe of the thyroid away from the trachea and opened the antero-lateral

aspect of the oesophagus. Having removed the foreign body, I closed the oesophageal wound and allowed the left lobe of the thyroid to fall back, placing a small drainage tube down to the oesophageal incision, and otherwise closed the skin wound. A temporary oesophageal fistula supervened, but healed within a fortnight; otherwise after-progress was uneventful.

The failure to remove the foreign body in this case by endoscopic methods was entirely due to lack of the necessary implements. External oesophagostomy in the face of modern appliances must now be regarded as unnecessary, if not almost bad surgery, when applied to foreign bodies of a non-penetrating variety; and when one contrasts the rapid recovery with the minimum of inconvenience to the patient of endoscopic methods, as compared with the more serious character of and prolonged convalescence from external surgical procedures on the oesophagus, the latter should be considered by all surgeons as out of date, unless the circumstances are very exceptional; such methods as blindly groping with probangs, etc., should only be mentioned to be condemned.

**CASE V.—Meccano Wheel Impacted in the Oesophagus Opposite the Third Dorsal Vertebra.**

The patient, a boy aged 6½, was admitted to the Portsmouth Eye and Ear Hospital on December 5th, 1922, with a history of having swallowed a meccano wheel, through which he was trying to whistle. The radiograph (Fig. 3) shows its position as stated above.

This is the type of case where up to recent years (and even possibly nowadays) a probang would be used to push the foreign body downwards, to be passed per rectum, with probably no great inconvenience to the patient; but the case with which it can be seen and removed by endoscopic methods, as was done in this case, with the elimination of any possible subsequent complications or damage to the oesophageal walls, still further renders the use of such instruments as the probang inadvisable when other methods are available. As regards the technique to be observed in endoscopic manoeuvres such as the foregoing cases entailed, the conclusions arrived at from these and other cases are as follows:

1. *Position of the Patient.*—If the manoeuvre is to be carried out under a local anaesthetic, which is only possible in a certain proportion of cases, the patient should sit on a low stool, with the head in the "sword-swallowing" position

—that is, extended fully, chin pointing upwards; if under a general anaesthetic, the patient should lie in the dorsal position, head over the end of the table, supported so as to bring the chin as nearly as possible level with the prominence of the thyroid cartilage. The patient as a whole should be on an inclined plane, head lowest, so as to obviate the occurrence which happened in Case 1, of the foreign body slipping back if escaping from the grip of the forceps.

2. *Before operation*, in the case of adults a hypodermic injection of 1/150 grain of atropine should be given fifteen minutes before commencing, and in the case of children under 12 years of age 5 to 10 drops of tincture of belladonna, according to the age of the child, by the mouth. This will

be found very useful in preventing undue accumulations of mucus. In nervous adults also 1/6 to 1/4 grain of morphine hypodermically will assist by calming the patient.

3. *Choice of Anaesthetic.*—As it is of great importance that the field of vision be unimpeded by collections of mucus, C.E. mixture, followed by pure chloroform, has been found of greatest service. In the case of adults, whose control is good, a local anaesthetic may be used with advantage; it will, however, take from ten to fifteen minutes to prepare the fauces and pharynx by painting with from 5 to 10 per cent. cocaine before complete tolerance is obtained, and a stimulant such as sal volatile should be at hand in case of fainting or collapse. Some distinguished endoscopists claim to use little or no local anaesthetic and to be able to induce their patients to allow them to pass their instruments. One regrets that one's own experience differs from this.

4. *Position of Surgeon.*—If the patient is under a local anaesthetic, the surgeon stands while the patient sits on a low stool. If the patient is under a general anaesthetic, the surgeon sits on a low stool—a dressing-box makes an admirable seat.

5. *Treatment of Tubes.*—The tube should be warmed and smeared with glycerin as a lubricant; a cold tube excites spasm.

6. *Lastly*—a small but practical point—if the surgeon is wearing glasses himself, these should be well warmed or smeared with Sterilla soap, otherwise he is liable to find his own vision fogged just when he most particularly wishes to see clearly.

FIG. 3.—Case v: Meccano wheel in oesophagus.

## "LUNG SPLINTING" IN THE TREATMENT OF PULMONARY TUBERCULOSIS.\*

BY

SAMUEL HENRY STEWART, M.D. EDIN.,

MEDICAL SUPERINTENDENT, BELFAST MUNICIPAL SANATORIUM, WHITEARBY.

This paper represents an attempt to work from evidence ascertainable by the clinician towards treatment in pulmonary tuberculosis. Practically any organ in the body may be attacked by tubercle; the frequency and course of the pulmonary lesion then raises the question of the significance of this particular condition. Fuller appreciation of Koch's experiments, which demonstrated the behaviour of immunized cells to tuberculous infection, forces the attitude that pulmonary tubercle is a phase in tuberculosis having defensive properties, and probably supplementing the lymphatic system in guarding against spread to other parts. This defensive element must receive consideration in treatment. The majority of serious therapeutic attempts have at their end the discovery of foci of immunity. This phase of treatment with marked febrile or other directions. The action there was of tuberculous. The swelling and to establish rest of the treatment. The dis-

cussion of the introduction of rest by lung splinting in the treatment of pulmonary tuberculosis can be dealt with most logically under three headings.

### I. *Facts which Point to Immobilization as being a Rational Procedure in Treatment.*

I first studied the deaths incident to the various tuberculous lesions. The following list, representing the deaths in a large Midland city, is cited as a basis of argument:

Pulmonary tuberculosis	...	...	...	1,171
Tubercle of abdomen	...	...	...	55
Tubercle of spinal column and joints	...	...	...	31
Tuberculous meningitis	...	...	...	74
Disseminated tuberculosis	...	...	...	40
Tubercle of glands and other parts	...	...	...	11

In the above table we notice that mortality from tuberculosis is mainly associated with organs whose function involves movement. Tubercle in what may be described as stationary organs accounts for a comparatively small number of deaths.

I next considered this association of tuberculosis and mobile organs clinically. To this end I divided up the various common lesions for comparison as follows: (a) Disease in the stationary organs—for example, glands; (b) disease in organs which are mobile but capable of being immobilized—for example, joints; (c) disease in mobile organs which are uncontrolled—for example, lungs. The large majority of cases falls into the third category.

These chronic types of tuberculosis soon

reveals the fact that natural or mechanical immobilization is not associated with anything like the systemic toxæmia or the incidence of metastases that are so common in cases of pulmonary disease. Those who have been associated with considerable numbers of patients suffering from progressive pulmonary tuberculosis and, say, osseous lesions, must have noticed that Nature can exert healing properties in the latter conditions when resting, while the pulmonary disease is slowly increasing. That this is due to secondary infections in the lung is improbable since the manifestations are those of tuberculous infections. Or again, it may be necessary to make allowance for tissue susceptibility, but, comparing one tuberculous joint immobilized with another free, there is little difficulty in deciding that movement is trauma—when it is in a joint. The fact I want to emphasize is that the introduction of movement produces a baneful influence.

As a corollary to this reasoning, if movement be a factor responsible for the progressive toxæmia and the spread of the disease to other parts of the body, then immobilization should unquestionably produce beneficial results. As far as toxæmia is concerned we have proof of the beneficial effect of low-tension artificial pneumothorax.<sup>1</sup> With regard to metastasis, trustworthy evidence of spread of disease from a lung whose respiratory excursion is restrained is not available.

There are probably several factors which determine the incidence of tuberculosis, but once disease is established movement would doubtless be of importance in causing extension to other parts of the lung or body, and, on the analogy of the tuberculous joint, would retard healing.

Again, let me remind the reader that one of the earliest manifestations of tuberculous disease in a joint is muscular rigidity—that is, Nature attempting to splint and produce rest. This same effort at restraint by Nature is also found in pulmonary disease, though less manifest. The reduced movement occurring over a diseased lung indicates the possibility of lung splinting, despite the bilateral character of respiratory movement.

With regard to the question of auto-intoxication, I think we may assume, considering the effect of immobilization, that the chief factor involved in the dissemination of tuberculous toxins is the respiratory disturbance of the diseased lung.

Consideration of these facts would suggest that treatment should have as its object the promotion of healing of the lung lesion and also the prevention of metastases and toxæmia. With this end in view it is absolutely necessary to produce a resting condition not only of the lesion, but also of the adjacent healthy, or comparatively healthy, lung tissue.

## II. Immobilization by Means of an External Splint.

If the introductory reasoning be regarded as sound, it is necessary to develop a means of immobilization which is applicable to the widest application. From time to time a means has been made to restrain or prevent lung movement. The most outstanding instance is that of artificial pneumothorax. Other methods of restraining lung activity have been employed, such as mechanical restraint by means of adhesive strapping or by a belt, introduced by Denison<sup>2</sup> and Sallow<sup>3</sup> respectively. Webb<sup>4</sup> has introduced rest of individual lung by posture. More recently Knopf<sup>5</sup> has suggested a method of pronounced diaphragmatic breathing by means of which respirations may be reduced to 5 to 10 a minute. All of these workers were convinced of the beneficial effects following lessened activity.

Working on the lines indicated I set about inventing a device which would take cognizance, at least to some extent, of the three factors in respiration—namely, rib movement, diaphragmatic movement, and lung movement. The device I have called a lung splint. Its character will be evident from a study of the accompanying illustration.

Left lung splint. Total weight = 2½ lb. A small elbow-lever on hip pad prevents perineal strap chafing right thigh. Fulcrum of supporting lever about point where spinal movements independent of pelvis cease.

All parts were suitably padded and made so light and comfortable that it was possible to wear the splint continuously. A light woollen garment was preferably worn next the skin. The patient expired completely and the straps were just comfortably tightened on the chest wall in this position, a small pad being used above and below the clavicle. The degree of immobilization was gradually increased, so that the patient became inured without any real discomfort. Notable features of this appliance are that the limbs have free movement; there is no vital impairment of the opposite lung; a certain amount of lateral spinal movement is possible, a striking feature being that leaning to either side increases the tension of the restraining belts. This apparatus was perfected by Messrs. Salt and Son, Ltd., 5 and 6, Cherry Street, Birmingham, and is manufactured by this firm.

## III. Effects of Lung Splinting.

The fact that tuberculous lesions in one part can exert healing properties while those in other parts are progressing unfavourably, would suggest that healing in tuberculosis is primarily a local effort. The effects, then, of a procedure which recognizes the importance of the local condition demand consideration. I shall indicate briefly how it appears to me restriction by means of this splint is effected.

By relaxation of the costo-sternal portion of the diaphragm contraction of the crus does not bring about the piston action which results in the lowering of the diaphragm. With regard to the ribs, these are intimately associated in producing enlargement of the thoracic cavity. Enlargement in turn causes expansion in all parts of the lung capable of functioning. Tendeloo's law is not now accepted, as Keith has shown that lowering of the diaphragm produces an effect even at the apex of the lung. No doubt the degree of expansion in different areas has some relation to the adjacent portion of the expanding mechanism. It is quite evident, therefore, that fixation of the ribs in the position of expiration together with impairment of diaphragmatic function will effect very considerable diminution of lung movement. Splinting takes

these facts into consideration and, what is equally important, recognizes the fact that rest which does not extend to the healthier part of the lung defeats its own object.

The first effect of lung splinting that has to be recorded is that it is possible to restrain lung activity. Respiratory function seems to fall mainly on the lower two-thirds of the free lung. The reader is referred to the spirometric readings, shown for each of the cases reported below. This opens up an interesting field of research in that the relative functioning of the lungs can be investigated.

Since my object in this preliminary investigation was not so much to publish results as to determine effects of splinting, I chose four afebrile patients who had been resident over periods as indicated below, and whose response to routine sanatorium treatment had been unsatisfactory or had been outlived. In this way contributory factors were eliminated as far as possible.

### CASE I.

J. J., male, aged 18; admitted January 14th, 1921. He was chosen because he was a case of pulmonary tuberculosis for whom apparently nothing could be done. His condition was getting worse. Right lung splinted March 13th, 1922.

Right lung splinted, 3,500.

Lung infiltrated with crepitations throughout. Crepitations in left lung, with slight infiltration of upper third. There was morning and evening cough. Sputum (twenty-four hours): 1 ounce; numerous tubercle bacilli. There was frequent pleuritic pain. Haemoptysis: Clots four months previously. Musculature poor; marked languor, and poor capacity for work; variable appetite; frequent night-sweats; marked dyspnoea. Blood pressure, 114/70.

Condition After Wearing Splint Seven Months.—A few crepitations in right lung, above clavicle and at lower apex. No moisture in left lung. No cough, sputum, tubercle bacilli, or pleuritic pain. Haemoptysis: Staining during influenza four months ago. The musculature was greatly improved; he felt fit for work; his appetite was good; there were no night-sweats, and the dyspnoea had greatly improved. Blood pressure, 125/80.

This patient has made phenomenal progress. The improvement in the left lung has probably something to do with the limitation of antero-posterior thoracic enlargement.

## CASE II.

T. W., male, aged 34; admitted July 19th, 1921. Chosen because he was a case of chronic bronchitis with clinical pulmonary tuberculosis. I thought sputum might be retained where the bronchial tubes were inflamed if immobilization were attempted. The condition was getting worse. He was particularly unsatisfactory at the time of splinting as he had just suffered from a sharp attack of influenza. Left lung splinted March 13th, 1922.

Spirometric Readings: Free, 3,006. Left lung splinted, 2,900. Right lung splinted, 2,470.

Condition Before Splinting.—Crepitations in left lung to sixth rib anteriorly and angle of scapula posteriorly. Rhonchi throughout chest. Cough troublesome in the morning. Sputum (twenty-four hours): 1 ounce; no tubercle bacilli. The musculature was good; there was marked languor, and poor capacity for work; appetite good; occasional night-sweats; marked dyspnoea on exertion. Blood pressure, 122/70.

Condition After Wearing Splint Seven Months.—Crepitations apex to second rib and in suprascapular region. Rhonchi throughout chest. No cough. Sputum, half an ounce; no tubercle bacilli. Languor gone, and capacity for work greatly improved; appetite good; no night-sweats; marked dyspnoea on exertion. Blood pressure, 124/80.

This patient claims that he feels greatly improved and is anxious to go out to work. No evidence of sputum retention.

## CASE III.

W. G. C., male, aged 19; admitted May 31st, 1921. Chosen because he was an advanced case having very frequent haemoptysis. The left lung was the more actively diseased, and I guessed the blood had its origin in this lung. He was very weak and the outlook was unfavourable. In addition infiltration in the right lung extended below the third rib. I was anxious to see what effect would be produced in the right lung if the left were splinted. Left lung splinted March 13th, 1922.

Spirometric Readings: Free, 2,210. Left lung splinted, 1,900. Right lung splinted, 1,755.

Condition Before Splinting.—Crepitations and infiltration throughout left lung; cavitation at inferior angle of scapula. Crepitations over upper half of right lung; less marked infiltration throughout. Cough severe in early morning. Sputum (twenty-four hours): 1½ to 2 ounces; numerous tubercle bacilli. Frequent haemoptysis; sometimes twice in same week. Musculature poor; marked languor; felt unfit for work; appetite fair; no night-sweats; marked dyspnoea. Blood pressure, 104/58.

Condition After Wearing Splint Seven Months.—Crepitations in upper half of left lung; evidence of fibrosis going on; cavity dry. Disease more active in right lung. Very slight cough. Sputum, 1½ ounces; few tubercle bacilli (both sputum and bacilli less at end of June). Free from haemoptysis up to July 10th; faint streaks occasionally since. Musculature improved; feels well; capacity for work improved; as also had appetite to end of June; dyspnoea not so marked. Blood pressure, 115/70.

This patient claims that he is no doubt is no doubt he made considerable progress up to the end of June. I noted then that the right lung was not so satisfactory. Sputum, etc., increased slightly. I am doubtful with regard to the ultimate result, though the feeling of well-being remains.

## CASE IV.

E. M., female, aged 28; admitted August 12th, 1921. Chosen because she was a well marked case of pulmonary tuberculosis showing evidence of failing resistance, also because she was physically frail. Left lung splinted May 1st, 1922.

Spirometric Readings: Free, 2,030. Left lung splinted, 1,920. Right lung splinted, 1,640.

Condition Before Splinting.—Marked disease with crepitations throughout left lung. A few crepitations at apex of right lung. Severe cough, causing vomiting each morning. Sputum (twenty-four hours): 1 ounce; tubercle bacilli fairly numerous. Haemoptysis once, nine months previously. Musculature poor; marked languor; poor capacity for work; appetite fair; marked dyspnoea on exertion. Blood pressure, 105/80.

Condition After Wearing Splint Five Months.—Left lung: Post-tussive crepitations only above and below clavicle and in suprascapular region. Right lung: No moisture. No cough. Sputum practically gone; no tubercle bacilli. Musculature good; fit for work; appetite good; dyspnoea greatly improved. Blood pressure, 110/72.

There is no doubt about the improvement in this patient.

The question of blood pressure is interesting. One would expect a certain lowering as a result of impaired thoracic movement. Having regard to this, and also the possibility of patients in the circumstances manifesting a certain amount of excitement, I am bound to say that I think there is room for feeling that the increase in pressure, especially diastolic pressure, is evidence of lessened toxæmia.

My object, however, was mainly to record effects, and this I have done as faithfully as I can. Perhaps I should emphasize that my observations do not include a claim that complete immobilization of the diseased lung is established. My contention is that movement would seem to be restrained to a degree approaching what might be termed rest. Excision

of a portion of the second rib as an adjunct is contemplated if necessary.

So far I am not sure that there are any contraindications to the use of this lung splint. Even in the very advanced Case III there is little doubt that the patient benefited. Apart from slight retraction of the side splinted no untoward effect noticed has escaped record.

## A FEATHER IN THE PAROTID DUCT.

In the abstract No. 168 of the *Epitome* of February 24th, on the subject of salivary calculi, reference is made to the possibility of a foreign body forming the nucleus of the concretion. This reminds me of an instance of a foreign body in the parotid duct, which is unique in my experience.

Some years ago a small child was referred to me at the Central London Throat and Ear Hospital on account of inability to open the mouth and the presence of a large painful swelling extending backwards and downwards from the right parotid region. The swelling was obviously an abscess on the point of bursting externally. I was able to force the mouth open sufficiently to allow me to see a small white object projecting from the orifice of Steno's duct. I pulled it out and found it to be the tip of a feather, which was about an inch in length. Evacuation of the pus by a simple incision was soon followed by complete recovery. The feather, which had evidently come out of the child's pillow, had been accidentally drawn into the mouth. The stem had entered the parotid duct, and the feather had apparently worked its way inwards in the same fashion as a spike of grass when put inside the coat sleeve, in the familiar trick of our childhood.

## MENINGITIS DUE TO PFEIFFER'S BACILLUS.

MENINGITIS associated with the presence of Pfeiffer's bacillus in the cerebro-spinal fluid is still sufficiently uncommon to deserve record. In the following case, as the cerebro-spinal fluid eventually became normal, it would appear that recovery ensued from the meningitis, the patient dying from pulmonary complications.

S. G., aged 62, had been operated upon twenty years previously for bilateral empyema of the antrum of Highmore; the sinuses were kept open by gold fillings in tooth sockets, and the patient continued to irrigate the antra daily. For the past five years he had suffered from recurrent attacks of nasal catarrh at very frequent intervals. The nose was examined, polypi diagnosed, and operation advised. At the time of removing the nasal polyp and operation what appeared to be a small deficiency in the cribriform plate of the ethmoid was noted.

Rigors occurred within a very short time of the operation, and three days later, the temperature having risen to 101.8° F., with pulse rate of 90, the patient began to complain of intense backache and frontal headache. His mental condition was normal, pupils small but active to light and accommodation, optic discs and other cranial nerves normal. The remaining physical signs were as follows: general cutaneous hyperæsthesia, slight rigidity of cervical muscles, no apparent spinal rigidity, Kernig's sign positive, abdominal reflexes sluggish, the five, knee and ankle jerks sluggish, abdominal withdrawal of the five, knee and ankle reflexes flexor with active withdrawal of the leg; heart and lungs normal. On lumbar puncture a turbid yellowish fluid under slightly increased pressure was obtained; when microscopically examined numerous polymorphonuclear cells and a few mononuclears were seen, but no organisms. On culture, Dr. Clement Lovell reported the presence of an organism showing the following characteristics: "A short Gram-negative bacillus growing only on blood agar or agar smeared with blood. Subcultures are more vigorous. A slight deposit in broth. The organism is maltose, or saccharose, a slight deposit in broth. The organism is non-pathogenic to the guinea-pig (Pfeiffer's bacillus)."

During the following week occasional delirium and retention of urine occurred, but the physical signs remained practically unaltered. Two doses of Pfeiffer's bacillus vaccine were administered, 5 and 10 million organisms respectively, the second dose being

given four days after the first. Lumbar puncture was performed and the intrathecal sac drained every other day, each successive sample of cerebro-spinal fluid withdrawn being less turbid than the preceding one.

After the first week the patient developed pulmonary complications and increasing drowsiness. The cerebro-spinal fluid, however, continued to become clearer to the naked eye and to show a decreased cell content; finally, fifteen days after the onset of meningitis, a perfectly normal sample was withdrawn. The general condition of the patient became worse, and he died on the twenty-first day of illness, apparently from bronchopneumonia. An autopsy was not permitted.

### ISOLATION OF B. ANTHRACIS FROM A SHAVING BRUSH.

Five years ago a malignant pustule developed on the cheek of a male after a few days' shooting in the veldt. The lesion appeared to develop on the site of an insect bite, and the condition was successfully treated in the Municipal Hospital, Bulawayo.

There has been anthrax in S. Rhodesia, but not of recent years, and infection might have resulted from camping on an old cattle kraal, or from the use of an infected shaving brush. The one which was in use had been purchased shortly before, and had been imported from Japan. The shaving brush was submitted to me in February of this year, and by placing the bristles in broth and incubating for forty-eight hours colonies were obtained on subculture which had the appearance of *B. anthracis*. Morphologically, too, the micro-organism resembled *B. anthracis*. A pure culture was obtained and a small quantity injected into two mice, both of which died within thirty-six hours. In both instances the spleen was much enlarged and diffident, and the bacillus was recovered.

The interest in this case lies in the length of time elapsing between the infection and the isolation of *B. anthracis* from the shaving brush, and illustrated the fact that an infected shaving brush is of potential danger for a very long time.

## Reports of Societies.

### TREATMENT OF CANCER OF THE TONGUE.

At the Medical Society of London on February 26th Mr. JAMES BERRY gave an address, preliminary to a discussion, on the treatment of cancer of the tongue. Lord DAWSON OF PENN presided.

#### Opening Paper.

Mr. BERRY commented upon the extraordinary differences of opinion as regards the details of operative treatment, and on the misleading character of many published statistics. The number of operations he had performed for the removal of the tongue in malignant disease—about forty altogether—was rather small, but he had at one time considerable opportunities of studying the pathology and clinical course of such cancers. He realized early that the ordinary mode of extension of carcinoma of the tongue was in a downward and backward direction towards the hyoid bone. Operations for the removal of primary growth should always extend widely in these two directions. He insisted on the necessity for free removal of the growth. Opinion was unanimous on the importance of early diagnosis and treatment. The public must be educated as to the importance of showing to a doctor any ulcer or growth that appeared on the tongue, and general practitioners must be impressed with the importance of not wasting time by attempting to treat suspicious growths by caustics or mouth-washes or other harmful or inefficacious remedies. Diagnosis presented little difficulty. Any doubtful ulcer should be excised and examined microscopically, and if found malignant treated forthwith by the larger operation, not by cauterization of any kind. He believed that he operated somewhat more willingly and freely in advanced cases of cancer than many surgeons; it was not that he operated with much expectation of permanent cure, but if the whole of the primary disease could be completely eradicated an extensive operation did afford to many patients who were in a miserable state of pain and distress a good prospect of speedy recovery for the time and immunity from suffering for some months.

He favoured the external or submaxillary operation, rather than the intraoral; to split the cheek to obtain better access to the posterior part of the tongue was an unnecessary mutilation, and to saw through the symphysis of the jaw seemed too severe, except perhaps for certain rare cases in which the body of the jaw was actually involved in the growth. He objected to the term "Kocher's operation," because the use of proper names for any operation was inadvisable, and because there were two distinct operations, both of which were known in the textbooks as Kocher's. The operation described as Kocher's submaxillary operation was widely different from the submaxillary operation which the speaker and other surgeons did at the present day, and he did not doubt that Kocher in his later days did not do anything like the textbook description.

Carcinoma of the tongue was essentially a local disease, with scarcely any tendency to affect distant organs. It tended, however, to infect at the earliest stage the nearest lymphatic glands, and if the growth originated in the anterior part of the tongue the removal of the glands *en bloc* could and ought to be performed when there was reason to fear such infection. If, however, the growth originated in the posterior part, the deeper cervical glands were those likely to be affected, and as they could not be removed *en bloc* a permanent cure was scarcely to be expected unless the primary growth was excised at a very early stage indeed. He had grave doubts whether so-called block dissection at one or both sides of the neck, which was very popular in certain quarters, was ever worth doing. It was not really a block dissection at all, but the picking out of certain lymphatic glands and ducts from among other structures which could not be removed. The procedure in early cases and cases situated in the anterior part of the tongue was seldom necessary, and in advanced cases, especially at the back of the tongue, was generally useless. He was by no means convinced that an unsuccessful attempt to dissect out the affected glands in the lower part of the neck did not often favour the spread of the disease.

Mr. BERRY then proceeded to give a list of 27 operations he had done in hospital during thirty years, all of them submaxillary, nearly always very extensive, and mostly involving the removal of one-half or the whole of the tongue, right back to the hyoid bone. He had had very few opportunities of treating early cases. He gave a detailed account of the large operation he had practised in these cases, his submaxillary operation differing in certain points of technique from that ordinarily done. He accompanied his description by photographs of the different stages of the operation done on a dead body. It was important that the mucous membrane should not be cut nor the mouth opened until all the muscles in the anterior and median portion of the tongue had been freely divided. A sponge must be put into the angle of the pharynx and the tongue to prevent what little blood there was trickling down into the pharynx. He indicated various other points and precautions. After the operation the patient should be got up betimes and made to wash his mouth out thoroughly. He usually told his patients that they had nothing else to do but to wash out their mouths, and for this purpose lotion and tumbler were by the bedside. He did not practise diathermy, and he did not wish to speak against it; but diathermy necessarily left the wound covered with a slough. It was of no use saying that it was a dry slough. It was dry at first, but within a week of the operation he could not understand how a slough of that kind could be other than septic.

#### Discussion.

Mr. CLAYTON-GREENE upheld the use of diathermy, which enabled him by an intraoral method to destroy the tongue right back to the epiglottis; diathermy also eliminated any possible chance of cancerous dissemination in the wound. By the time the slough became septic the lymphatic spaces of the neck were shut off by their natural protection. Mr. HAYWARD FISCH spoke of the value of radium, though he admitted that absolute cures were extremely few, if they occurred at all. He instanced three cases of continuing good results from the insertion of small powerful emanation tubes. Mr. GORDON TAYLOR said that he performed the much decried block dissection of the neck, the extirpation of the tongue itself being carried out at a subsequent operation. Where there was any extension of the growth to the floor of the mouth he did not hesitate to split the jaw and wire the bone again at the end of the operation.

Mr. A. EDMUNDS said that he had recently, to his disappointment, to do a second operation on his most successful

case, which had gone on so long—fourteen years—after the removal of half the tongue that the patient's friends were saying that it could not have been cancer at all. The man had returned with growth on the tip of the tongue, unquestionably malignant, but, fortunately, still removable.

Mr. H. S. CLOGG said that he had given up the so-called block dissection; he divided across the sterno-mastoid, and made a direct attack upon that region of the neck which lay round about the mastoid and the belly of the digastric muscle, and if any glands were enlarged he had no hesitation in excising. Mr. CECIL ROWNTREE had found results disappointing; it did not seem to make much difference what kind of operation was done. This was the most hopeless kind of cancer, and apparently only palliative measures could be attempted. Mr. W. G. SPENCER pleaded that the general practitioner should take more seriously any lesions in the mouth. Dr. LAPHORN SMITH was convinced that the new attention to dental hygiene would make cancer of the tongue an extremely rare condition in the future.

Mr. BERRY, in replying, remarked that little had been said about results, and he suspected they were extremely bad. He knew of only two cases which had survived more than five years. His most successful case was that of a medical student who had a small epithelioma on the side of the tongue which he had only noticed for six weeks. Half the tongue was removed, and, two months later, the glands in the submaxillary; the patient had no return whatever, but, five and a half years later, died of epithelioma of the lower end of the oesophagus.

### DIABETES INSIPIDUS.

A MEETING of the Medical Section of the Royal Academy of Medicine in Ireland was held on February 16th, with Dr. O'CARROLL (in the absence of the President, Dr. T. G. Moorhead) in the chair. Dr. F. C. PURSER showed a middle-aged man who had been suffering from diabetes insipidus for about four years. The smallest quantity of urine passed in twenty-four hours was 480 oz.; the average was 520 oz.; on an average 34 oz. were passed at a time. The patient was feeble and thin, and much bothered with frequent micturition, but no evidence of disease of any sort other than the diabetes could be elicited. Professor Scott had demonstrated inosit in the urine. Thyroid extract had been administered without any result, and pituitrin had been tried for several days hypodermically without any appreciable effect. Cerebro-spinal fluid, to the amount of 7 c.cm., was withdrawn after the failure of the pituitrin: the fluid was perfectly normal, its Wassermann reaction was negative, and the pressure was not excessive. The patient suffered no unpleasant symptoms afterwards, but the quantity of urine passed rose to a very constant 640 oz. in the twenty-four hours. Dr. CROFTON thought that if thyroid extract was given in bigger doses, in severe cases such as this it might prove beneficial. Dr. G. E. NESBITT said that the results obtained by pituitary extract in many of these cases seemed very striking; he was of opinion that specimens on the market must be often inert, and they were apt to forget this in case of failure. He suggested that Dr. Purser should try a different brand of pituitary extract in the case. Dr. O'CARROLL and Dr. KIRKPATRICK also discussed the case.

Dr. J. O'DONNELL showed a patient aged 70, who, while under treatment for chronic nephritis, developed herpes zoster associated with considerable pain in the distribution of the fifth to the eighth cervical areas on the left side. This was followed in the course of a few days by atrophy of the muscle of the shoulder girdle. Subsequently there was some herpes in the region of the distribution of the seventh cervical area on the right side, but this was not followed by muscular atrophy. The condition of the patient was improving slowly. Sir JOHN MOORE said that he thought there was not much doubt regarding the diagnosis of the case, as it seemed to him to be almost certainly a case of anterior and posterior myelitis. Dr. F. C. PURSER said that he had treated a somewhat similar case, who died about two years afterwards from myelitis.

Dr. H. F. MOORE read a paper entitled "Insulin and diabetes—the present position." He made a comprehensive survey of the literature to date; the ideas conceived in 1920 by Banting were explained, and the work carried out by Banting, Best, Collip, and others in Macleod's laboratory in Toronto on the preparation and study of active pancreatic extracts was described. The various stages in the experimental work on the improvement of the methods of prepara-

tion of the extract and the possibilities for the future in this direction were discussed. The physiological actions of insulin on the lowering of blood sugar, abolition of acidosis and glycosuria, and the raising of the respiratory quotient were discussed, as well as its use and possible abuses in the treatment of diabetes mellitus. The importance of dietetic treatment in conjunction with insulin was emphasized. Some experiences of the author with cases of diabetes treated with insulin were mentioned.

The paper was discussed by Dr. O'CARROLL, Dr. CROFTON, and Dr. G. E. NESBITT.

### DEEP X-RAY THERAPY IN GYNAECOLOGY.

A MEETING of the Obstetrical Section of the Royal Academy of Medicine in Ireland was held on February 23rd, with the President, Dr. BETHEL SOLOMONS, in the chair.

Dr. G. E. PEPPER read a paper on deep x-ray therapy as used in the Schauta Klinik, Vienna. He described the "symmetrie" apparatus devised by Professors Seitz and Wintz of Erlangen, the essential points being the division of the coil into two symmetrical parts, and the inclusion in the circuit of two water-resistance tubes, with an enclosed point and plate spark-gap so as to destroy all oscillations and inverse currents and to prevent formation of poisonous gases. The various instruments used for measuring the dosage and the method of estimating the penetration of the rays by means of the water phantom were described, emphasis being laid on the great difficulty and importance of these preliminary calculations. The dosage table formulated by Seitz and Wintz was quoted, and the method explained by which a carcinoma dose could be given to a tumour 10 cm. deep, by irradiating over six different fields of the abdomen. The importance of accurately centring the tube in each field was pointed out. The susceptibility of the different patients to radiation was referred to, and the great necessity of making a blood count before each treatment, owing to the destructive action of x rays on leucocytes and red corpuscles. The Vienna method of treating carcinoma of the uterus, with its advantages and disadvantages, and the application of x rays in cases of essential bleedings, amenorrhoea, menopause, and myomata were described. X rays were compared with radium in the treatment of malignant disease, and the combined use of both was advocated in order to obtain the best results. The action of x rays on malignant cells was said to be due to ionization, which caused lecithin to split up and liberate cholin, which poisoned and killed the cells. Cholin was set free in the very cells where its action was required, because malignant cells and tissues particularly sensitive to x rays, such as the testicles and ovaries, contained higher percentages of lecithin than other tissues.

Dr. W. C. STEVENSON said that a great deal of constitutional disturbance occurred when x-ray and radium treatment was being given—in his opinion as much as after an operation. It took a great deal out of a patient to get thorough treatment from x rays or radium, and it did not give him a proper chance if he only had one treatment; he should have at least two or three treatments. He thought if the growth was extensive there was a chance of increasing it by radiation, unless deep x-ray therapy was used; unless the dose in these cases lasted for eight hours he did not think it would do much good. A great number of patients in whom the cervix alone was involved were operated on, though in America as good results were obtained with radium alone, or combined with x rays, as by operation. Dr. L. L. CASSIDY said that his experience in hospital regarding radium had been rather unfortunate, as in two cases its application had appeared to stimulate the growth, although in another case of inoperable carcinoma the patient was very much improved.

Sir ANDREW HORNE said that the effect of x rays in stopping haemorrhage was undoubtedly wonderful. He had had one patient in whom, at the time the x rays were given, the condition was desperate, but the giving of x-ray treatment prolonged her life for a year, and made her feel much more comfortable. He agreed with Dr. Stevenson about the constitutional effects produced by x rays, as this patient suffered from a great deal of pain after treatment, which had to be relieved by the injection of morphine. Dr. G. TIERNEX said that, according to Erlangen technique, an eight-hour dose of x rays was not strictly correct; but on that matter

they might have different opinions in Vienna from Erlangen. In Erlangen Coolidge tubes were now used exclusively, and with them the unit skin dose was obtained in a little over twenty minutes. He was of opinion that in some cases constitutional reaction was severe, but he thought it was never anything so severe as it was after operation. Generally speaking, there was no difference between x-ray and radium treatment, and the indications for radium treatment were exactly similar to those for x-ray treatment; the contra-indications also were identical. The advantage radium had over x-ray was that screening was much more effective. The constitutional symptoms were much more marked in x-rays than in radium.

The PRESIDENT had read of collapse and anaemia following the Erlangen treatment, and he inquired if these were usually present, and also if prophylactic transfusion was often done. He believed that the x-rays often stimulated potential cancer cells, and his feeling was that when a growth had been satisfactorily and entirely eradicated post-operative x-rays were dangerous for this reason. He thought the treatment of fibroids by x-rays was incorrect, unless in exceptional circumstances. There was no method of excluding malignant degeneration, and he had published several cases of inoperable malignancy following the x-ray treatment of fibroid. The difficulty in insisting on hospital patients returning for radium treatment in cancer of the cervix made the results of the treatment difficult to complete.

Dr. PEPPER, in reply, said that undoubtedly constitutional effects were produced after the application of x-rays, but they did not last, and often the patients were able to return home in two or three days, whereas after operation they could not return for three or four weeks. Emanations were not used in Vienna, as they had such a considerable stock of radium; gas tubes were also used entirely, as they were much cheaper than Coolidge tubes.

Dr. R. E. TOTTENHAM exhibited a modification of the Rotunda siphon douche, which he stated was cheaper than the Rotunda siphon douche, and had the advantage that if any part of the rubber gave way it could be renewed without purchasing a whole new douche. Sir ANDREW HORNE showed two specimens, the first a malignant ovarian tumour, and the second a fibro-cystic tumour. Dr. GIBSON FITZGIBBON showed a specimen of a septic uterus. Dr. A. H. DAVIDSON read a paper on a case of traumatic subcutaneous emphysema complicating labour. Dr. L. L. CASSIDY read a paper on a rare case of maldevelopment of the female genital organs, and showed specimens.

### "PINK DISEASE."

A MEETING of the Midland Medical Society was held in the Medical Institute, Birmingham, on February 14th, when the President, Dr. PUNSLow, took the chair, and some fifty-two members were present.

Dr. PARSONS showed a case of "pink disease" (erythredema). He gave a short summary of the literature of the disease, and stated that he had seen six cases. All had suffered from the condition for many weeks, but previous to the onset of the disease had been well nourished and healthy children. The outstanding symptoms in this series of cases were: (1) The presence of a rash varying in degree and character, but always accompanied by intense itching; (2) red, swollen, and cold feet and hands, showing desquamation; (3) striking mental changes, the patient often presenting a picture of the most intense misery; (4) gingivitis and stomatitis, with falling out of the teeth; (5) a varying degree of hypotonia and pseudo-paralysis; (6) the frequent occurrence of respiratory disorders; (7) the liability to sudden death.

Dr. G. H. NELSON showed a man who had complained of severe pain in the left side for several months. This man had been seen by several surgeons and physicians, without a definite diagnosis being made. X-ray examination was negative. The pain was eventually found to be due to a loose costal cartilage on the ninth rib, which was removed, and a complete cure resulted. Dr. LEONARD PARSONS described a similar case following an accident, in which the fourth costal cartilage was separated from its rib, causing severe paroxysmal pain; this case recovered without operation.

Dr. O. KÄUFFMANN exhibited the organs from a case of lymphadenoma. Blood films and microscopic sections from the same case were shown on the epidiascope. Dr. J. G. EMANUEL read a paper on the treatment of auricular fibrillation by quinine sulphate.

## Rebels.

### A HISTORY OF MILITARY MEDICINE.

THE remarkable series of *Notes on the History of Military Medicine*,<sup>1</sup> which appeared in the *Military Surgeon* between November, 1921, and August of last year, have been reprinted in a convenient pamphlet of 206 pages. They were originally intended for the information and instruction of medical officers of the United States army, and are an expansion of two lectures delivered by Lieut.-Colonel FIELDING H. GARRISON at the Field Medical School in Pennsylvania in June, 1921. The author has had at his disposal the matchless treasures of the Surgeon-General's Library at Washington, the Index Catalogue of which has now reached its fortieth volume and contains a list of some 600,000 books and pamphlets. Into this vast bibliography Colonel Garrison has dipped deeply, and his notes will be read with profound interest by all who are attracted by the fascinating study of the origin and results of wars throughout the ages; for he does not confine himself to describing the details and various stages in the practice of medicine, surgery, and hygiene in connexion with campaigns, but enlarges in clear language on the circumstances and psychologies which gave rise to and resulted from the conflicts of peoples from the earliest times to the present day. Although he has thus explored the literature of his subject widely and draws on historians, novelists, and poets for apt quotations and illustrations, his notes bear evidence of having been largely culled from the writings of Frölich, one of the surgeons-general of the Saxon army from 1895 to 1900, and a warm personal friend of Colonel Billings, formerly librarian of the Surgeon-General's Library. Frölich was the most prolific of all writers on the history of military medicine, and embodied most of his studies in his treatise *Militärmedizin* published in 1887. One of his most remarkable achievements was to make out a list of all the wounds mentioned in the *Iliad*, 147 in number, and classify them according to weapon, anatomical region, and total and percentage mortality. Incidentally it may be doubted whether Colonel Garrison is correct in the meaning given to the Homeric *ιγρός* as an "extractor of arrows," as if derived from *ίός*, an arrow. The more correct derivation is probably from *ίάσμαι*, to heal, and *ιγρός*, or *ιαρός*, thus means "healer."

Colonel Garrison devotes a chapter to the practice of medicine in prehistoric times, in ancient Egypt and Greece, and in the Assyro-Babylonian, Jewish, and Indian civilizations. It is followed by an account of the status of military medicine under the Roman Republic and Empire, the battle losses, the organization of the Roman army and the establishment of a medical service in it, Roman military hospitals and military sanitation. Passing to mediaeval times, Colonel Garrison gives England the credit of being the first to attempt an organized military medical service, at the time of the crusades. Efforts were also made to organize a public health service in the Middle Ages, when wandering soldiers and outlaws were spreading diseases of all kinds amongst the squalid and crowded populations of the walled towns. In these efforts "rulers, physicians, and public officials did their best work." Carriers of disease were isolated; they were prevented from entering the towns, and lazarettos were established. Another interesting record of this period is the organization of camp hospitals and an ambulance service by Queen Isabella of Spain during the wars with the Moors. The Queen herself visited the wounded in the field, and her chronicler, Dr. Withington, described her as the "*mater castorum*."

The sixteenth century, or the period of the Renaissance, produced Ambroise Paré, whom Colonel Garrison regards as the greatest of military surgeons. It was a time when prostitution prevailed on a very extensive scale and syphilitic diseases were rife; it was followed by a period of continuous wars, devastating diseases, and starvation. A Polish knight, Abraham a Gehema, then arose to denounce the indifferent care of the sick and wounded soldier by "the half-baked medical personnel of the period." Colonel Garrison describes him as a "notable exhorter and hot gospeller of the soldiers' welfare."

In the eighteenth century military medicine became a definite function of governments. The outstanding figures of

<sup>1</sup> *Notes on the History of Military Medicine*. By Lieut.-Colonel Fielding H. Garrison, Medical Corps, United States Army. Washington: Association of Military Surgeons. (10 in. x 7½ in., pp. 206. 1.50 dol.)

the period were Frederick the Great, Marlborough, and the Maréchal de Saxe, all of whom took an intense personal interest in the medical work of their armies. But Colonel Garrison omits to mention the influence of Joseph II of Austria, who of all other monarchs of his time was the most noteworthy in connexion with army medical organization. It was he who with the advice and assistance of his body surgeon, Brambilla, completely transformed the character and training of the army medical service and introduced a field medical organization, which Brambilla's successor, Sax, developed during the Napoleonic wars into that system of collection, evacuation, and distribution of wounded that was afterwards adopted by all the Continental armies and also by the British Army in more recent times. Yet Colonel Garrison makes no reference to these famous military surgeons or to the institution of the great military medical school in Vienna, the "Josephinum," founded by Brambilla in 1785; and he names as the greatest of military medical officers Baron Larrey, of Napoleon's day, and Letterman, the medical director of the Army of the Potomac in 1862. Most of us would regard Brambilla's and Sax's influence on army medical organization as greater than theirs.

Again, there is no mention of the famous Sir James Wyllie (Baron Willy of Russia), who was the head of the Russian army medical services during the Napoleonic wars and founded the medical academies at St. Petersburg and Moscow in the reign of Alexander I, and who was a graduate, like his contemporary, Sir James McGrigor, of Aberdeen University.

In describing the wars of the nineteenth century Colonel Garrison gives a full and interesting account of the medical, surgical, and sanitary work of military medical officers and of the results of the great military advances in scientific knowledge of disease. The last chapter of his Notes is devoted to "the European war" of 1914-18. He introduces it with a dissertation on the philosophy of Nietzsche, which is described as "once a private luxury of antique despots and more recent artists and literary virtuosi," but became a dangerous dynamite in a society based on industrialism and inimical to the principle of "the greatest good of the greatest number" upon which modern medicine, sanitation, and social endeavour are based. A table is given of the battle losses during the great war in all nations, amounting to a total of killed, wounded, and missing of 34,299,314 out of a mobilized strength of 61,140,177. According to this table the Russian losses were greatest, exceeding nine million, the German next, nearly seven million, the Austrian over five million, the French over four million, the British three, and the Belgian just under three million. The United States lost 351,207 out of 4,175,367 mobilized. It is difficult to gauge the accuracy of these and other statistics given by Colonel Garrison, but they are no doubt supported by documentary evidence. Unfortunately he is not free from the common error of his contemporaries in substituting for well-understanding facts.

... famous march to the ... miles in 86 days. The march commenced on March 19th, 1704, and the battle was fought on August 13th. Colonel Garrison has evidently taken the 86 days covered by these dates as days of continuous marching and calculated the distance by multiplying the number of days by a daily march of 13 to 14 miles, whereas the celebrated march ended on June 27th at Gingen, within striking distance, 20 to 30 miles, of Schellenberg and Blenheim, and covered a distance of some 300 miles only in less than six weeks. Again, he quotes Sir John Goodwin as estimating the casualties among Regular and Territorial medical officers as 23,504 during the recent great war, of whom 3,181 were killed in action, 1,429 died of wounds, 1,887 of disease and other causes, and 17,007 were wounded, figures which Colonel Garrison says make an impressive showing. An impressive showing indeed, but happily untrue. Sir John Goodwin's figures refer to all ranks of the R.A.M.C., and not to officers only, of whom 743 were killed or died of wounds or disease. The statement that Great Britain was forced to adopt compulsory service on May 25th, 1915, is erroneous. There are several other errors regarding the British medical services. The British entry into Baghdad in March, 1917, is attributed to Allenby's invasion of Palestine. But this invasion did not take place till October of that year. Rutherford Morison, the inventor of bipp, is called Rutherford Brown. The meningitis incidence is stated to have been lowered by vaccination and "even dysenteries were rendered comparatively innocuous through preventive vaccination." This was certainly not the case in the British

Army. There are also several statements which suggest some misunderstanding of the strategical and tactical employment of the medical services during the war. Such are his remarks regarding the origin of the casualty clearing station, which was due to the faulty reorganization of the field medical units after the South African war and not, as stated by him, to the organization of these units during that war; and his remarks to the effect that they were able to come closer to the front line during the final advance to victory and the onset of mobile warfare are due to misapprehension, for the contrary was the case. Barrage fire he seems to have regarded as a screen which enabled the stretcher-bearers to collect the wounded during daylight, as if this had not been done previously. On the whole, however, the interesting figures which he gives of the incidence of disease amongst the United States troops justify the remark that they show "the extraordinary advances made by preventive medicine in the twentieth century."

W. G. MACPHERSON.

#### PERICARDITIS.

THE monograph on acute pericarditis by Dr. GERMAIN BLECHMANN<sup>2</sup> will be of considerable interest to British readers. The subject is dealt with in a very comprehensive manner, and, though there are many references to the writings of many workers in France and other countries, the author takes a judicial attitude and expresses his opinion in a way which suggests careful thought and wide experience. Some of his statistical tables indicate the need for fuller knowledge and more accurate methods of diagnosis of this disorder. When out of 238 cases collected from four London hospitals only 40 per cent. were diagnosed during life, and of 100 cases of purulent pericarditis in children under 12 years only 6 per cent. were so recognized, Boraïd's statement that there is no malady of a similar gravity so frequently discovered for the first time in the post-mortem room seems amply confirmed.

In discussing the etiology of this affection the author finds it convenient to treat four different age periods separately—namely, to the end of the second year, when pneumonic conditions prevail; from 2 to 15 years, when rheumatism, pneumonia, scarlatina, and other septic conditions predominate; from 15 to 30 years, when pneumonia, tuberculosis, and septicaemia give rise to most cases; and after 30 years, when Bright's disease and other debilitating diseases make their influence felt.

The section of the book dealing with the signs of pericardial effusion is very instructive, and the various signs are discussed from both the experimental and the clinical aspect. One sign which must have been more frequently quoted in France than in this country has led the author into an historical by-path of some interest. We have referred to the matter (September 16th, 1922, p. 522) in a note on a paper Dr. Blechmann had then recently published, but the story is so interesting and instructive that its main points may here be repeated. Sibson's notch (*l'encoche de Sibson*), an obtuse angle in the left border of the dullness, has apparently been noted at examinations by a generation of French students as a first and decisive sign of pericardial effusion, since attention was drawn to it by Potain in 1867. The author was unable to find a description of any such notch in Sibson's writings, but found instead that he stated that the pericardium when distended with fluid encroaches on the left lung. He believes that this word has been erroneously translated as *encoche*. The term has, in this country at least, practically disappeared from current descriptions, and is not of diagnostic value, being present in other conditions. The interest lies in the fact that a sign of at most doubtful value should have been introduced into France with a faulty English title, been reimported into this country, and finally laid low in the country of its illegitimate birth. All the ... with a similar thoroughness, and much ... the views of Ewart. Those which seem to appeal to the author most are dullness in the fifth right intercostal space, the angle which the right border makes with the liver dullness, the symmetrical increase in cardiac dullness, and the patch of tubular breathing and aegophony at the angle of the left scapula. It is unnecessary to dwell further on the other signs and symptoms which are described and analysed. No part is left undone.

<sup>2</sup> Les péricardites aiguës. By Dr. Germain Blechmann. Paris: Ernest Flammarion. 1922. (Cr. 8vo, pp. 282; 27 figures. Fr. 10.)

We would draw attention to the author's method of exploring or aspirating the pericardial sac. After an exhaustive investigation into the position taken by the fluid as determined after experimental and clinical observations, he strongly recommends the procedure first practised by Professor Marfan in 1911. The epigastric route is chosen, the needle being inserted in the middle line under the tip of the xiphoid. For the first two centimetres the needle is kept close to the under surface of the bone, and thereafter it is advanced a little obliquely from below upwards through the cellular tissue till it penetrates the pericardial sac. It has been demonstrated that a small quantity of fluid is most likely to be found at this part, and that the danger of puncturing the heart is much less than by the other routes that have been suggested. For exudates found to be purulent the various surgical procedures are discussed.

The book will be found to contain much valuable information, and we have much pleasure in recommending it to our readers.

#### PHYSICAL EXAMINATION OF THE CHEST.

In his book entitled *Physical Examination of the Chest*,<sup>3</sup> Dr. JAMES CROCKET has gathered together into a compact form a series of lectures customarily delivered to students. As becomes such lectures, they are characterized by directness, lucidity, and dogmatism. Careful classification, frequent headings and subheadings, and divisions annotated numerically combine to produce perfect clarity, and to avoid that confusion which is only too frequently the bane of the most eminent clinicians. The arrangement is straightforward, commencing with a description of the surface anatomy of the thorax, followed by a chapter each dealing with inspection, palpation, percussion, and auscultation. There follows a description of the radiographic examination of the chest, in which particular attention is paid to the appearances manifested in its earliest stages by pulmonary tuberculosis. The insertion of a chapter on laryngoscopy, containing a valuable differential diagnostic table between tuberculous and syphilitic lesions, is amply justified by the importance of the indications so often afforded by affections of the throat. Finally, various classifications of pulmonary tuberculosis which have been suggested, including the Turban-Gerhardt classification and that of the National Association of America, are very suitably added in conclusion.

From the student's point of view especially the book should prove of the greatest value. The subject under consideration is adhered to strictly throughout. The author writes as a clinician, and himself exhibits and encourages others to exhibit those qualities of careful observation and attention which are so difficult to acquire in the present state of crammed curricula and abundant subjects of subsidiary or specialized importance. In its directness, its conciseness, and its eminent readability, the book reminds us of the classical writings of Dr. Gee, and we wish it all the success which attended the works of that famous physician.

#### BACTERIOLOGY: GENERAL, PATHOLOGICAL, AND INTESTINAL.
